Smock Mills. Smock mills (named after the dress-like agricultural costume whose shape they vaguely resemble) are a fundamental improvement over the post mill design.

Instead of rotating the whole body of the mill to face the mill, the smock mill design consists of a fixed wooden body, holding the milling machinery, together with a rotatable cap, which holds just the roof, the sails, the windshaft and the brake wheel.

By rotating just the mill cap, the body of the mill can be made much larger than in a post mill, and hence able to house more pairs of stones, and more ancilliary machinery. In addition, the body can be made arbitrarily high, the extra height allowing the sails to catch more wind (and to a certain extent a taller body can allow longer sails to be employed, to the same end).

Smock mill bodies are theoretically roughly circular, though the use of straight timber means that most are actually eight sided. Other numbers of sides occur, including in England examples of six through to twelve sides. (In addition there are a number of small smock mills throughout the world which have square bodies).

Smock mills exist in Western Europe and particularly in England, where they were common, particularly in the county of Kent. They reached their heyday in the earlier part of the 19th century, after which the advent of steam power started the decline of the windmill.

Tower Mill. Tower mills take the smock mill design even further, by replacing the wooden body with a brick or stone built tower. Since the necessity of having straight sides (due to straight timber) is removed, true circular bodies are the common arrangement. However straight sided structures do occur, and even towers that start off with straight sides at the base, but change to a circular plan part way up.

By using brick or stone for the body, tower mills can be built even larger and taller than smock mills, and by being a more durable building material, the mills are more weatherproof.

The advantage of the Tower Mill over the earlier Post Mill is that it is not necessary to turn the whole mill with all its machinery into the wind; this allows more space for the machinery as well as for storage.

In the earliest tower mills the cap was turned into the wind with a long pole which stretched down to the ground at the back of the mill. Later an endless chain was used which drove the cap through gearing. In 1745 and English engineer, Edmund Lee, invented the fantail–a little windmill mounted at right angles to the sails, at the rear of the mill, and which turned the cap automatically to bring it into the wind.

History

The first documented use of windmills was in Persia around 500–900 A.D., however, it is widely accepted that they were invented in China more than 2000 years earlier. In these early windmills, vertical-axis systems were used for grinding grain and pumping water. In the vertical-axis system, the wind would have to hit the mill from a specific angle to get the desired effect; therefore, most of the area around the mill had to be shielded. Later, horizontal-axis systems were developed that proved to have greater structural efficiency. By tilting the blade to a certain degree, the system

eliminated the dependence on the direction of the wind and harnessed the wind energy lost in the vertical-axis systems by the areas shielded. Horizontal systems were later used throughout Europe.

Windmill technology, it is believed was introduced in Europe in the eleventh century. The earliest mills were probably grinding mills. They were mounted on city walls and could not be turned into the wind. Because fixed mills did not suffice for regions with changing wind directions, mill types that could be turned into the wind were developed. With some subsequent development mills became versatile in windy regions for all kind of industry, most notably grain grinding mills, sawmills (late 16th century), threshing, and, by applying Archimedes' screws, pumping mills.

They soon became the major energy source in the low lands, where the older watermills could hardly operate due to the lack of height difference in the water ways. The pumping mills allowed the drainage of the Dutch wetlands to claim new land, polders. By continuously pumping water out to the rivers, land below sea level could be created. The earliest Dutch polders date from the middle ages, the first lake was emptied by Jan Leeghwater from 1607. To claim ever more land it became necessary to build series of mills (molengang, mill pace), because an Archimedes screw can only efficiently pump water for a limited height. Each mill pumps water into a higher reservoir, with the last pumping it out to the river.

Another region well-known for its windmills is La Mancha, Spain. The windmills of La Mancha were made particularly famous by a scene in Cervantes' *Don Quixote de La Mancha* where the title character mistakes them for giants sent by an evil enchanter, giving rise to the phrase "tilting at windmills".

With the industrial revolution, the importance of windmills as primary industrial energy source was replaced by steam and internal combustion engines. Polder mills were replaced by steam, or diesel engines. More recently historic windmills are being preserved for their historic value, which requires regular use because the wooden machinery is likely to be destroyed by maggots when the mill remains stationery for too long. With increasing environmental concern, and approaching limits to fossil fuel consumption, wind power has regained interest as a renewable energy source. These new generations of windmills produce electric power and are more generally referred to as wind turbines.

As Europeans sought to expand and colonize, they brought the windmill technology with them. The colonization of the Americas is a prime example. Without this technology, it would have been impossible for immigrants to settle in areas that lacked a constant water supply. Certain areas in Texas, for example, lacked the needed water supply to sustain life and allow cultivating of the land. The drive to expand into these areas helped to stimulate the need to refine the windmill to solve this problem. Daniel Halladay addressed this problem in 1854 by changing the European windmill so it could operate unattended and more efficiently. The changes that he made appealed to many companies and small communities without water systems by providing an inexpensive way to get the water they needed (Fig. 1.)

Fig. 1. Windmill on farm in Sheridan County, Kansas. (*courtesy of the Farm Security Administration/Office of War Information*).

The multi-bladed wind turbine atop a lattice tower made of wood or steel was, for many years, a fixture of the landscape throughout rural America (Fig. 2). These mills, made by a variety of manufacturers, featured a large number of blades so that they would turn slowly but with considerable torque in low winds and be self regulating in high winds. A tower-top gearbox and crankshaft converted the rotary motion into reciprocating strokes carried downward through a pole or rod to the pump cylinder below.

Fig. 2. A modern day windmill in California.

The Wind Pump: How It Works. The wind pump has four main features the wind turbine, the tower, the actual pumping equipment, and the storage basin. These parts can be found in almost all wind pumps. They vary in design depending on the wind conditions in which they will be used. If the wrong design is used in strong wind conditions, the pump may move too fast and malfunction, and if the wind speed is low, it may not be able to function at all.

The horizontal-axis is the typical system used for wind turbines to pump water. The rotor does not have to follow any specific design but instead should be designed for the wind conditions in which it will be used. However, the pump tends to have more force when there are more blades. The next main part of the wind turbine is its transmission. The transmission of a wind turbine converts each rotation of the rotor into an up and down motion, driving the pump rod in and out of the well. The tail of the wind turbine is a piece that was added during the westward expansion in the United States. It allows the wind turbine to work without constant supervision by changing the direction of the rotor to keep it facing the wind.

A tower holds the wind turbine generally between 10 m (33 ft) and 15 m (49 ft) high. It holds up the wind turbine and stabilize its connection with the pumping parts of the machine. The tower has either a square or triangular base, and the pump rod that moves in and out of the well is positioned in the center of the tower. The well that the pump rod enters can either be a shallow hand-dug well or a deep-drilled well. If the latter is the case, the walls of the well should be lined with a water permeable material to prevent them from caving in. A pipe called the rising main lies in the center of the pump rod. Its function is to carry the water pumped up to the surface. The actual pump is at the bottom of the pump rod submerged

in the water and is attached to the rising main. The pump fills with water during the downward motion of the pump rod and pushes the water into the rising main and up to the surface as the pump rod moves up.

Finally, all wind pumps should have a storage basin that can hold the excess water that is pumped. When the water moves up into the rising main, it is then redirected into the storage tank. This stored water is also essential to water pumping systems because wind energy cannot always be relied on, and having a surplus at hand is useful.

The Advantages and Disadvantages of Wind Pumps. There are many advantages to using wind energy for pumping water. First, wind pumps are environmentally friendly. As with the atmosphere, wind turbines will not contaminate the land, and in the case of water pumps, there is no chance the water will be contaminated as a result of a malfunctioning wind pump.

Wind turbines generally do not affect the wildlife that inhabits the area. Sheep, cattle, deer, and other wildlife are not bothered by the turbines, and in fact have been known to graze under them. The only argument that has been raised about this issue is the tendency for birds to collide with them. However, several studies suggest that the impact of the wind turbines on birds does not compare to that of other things, such as electrical lines and buildings.

Wind pumps are cost-efficient. After the initial cost of installation, the owner basically has an infinite source of energy for just the cost of maintenance. Whereas using a fossil fuel to work the pump would make the owner subject to its cost.

There are, however, a few setbacks in using wind energy for pumping water. Because the wind is not reliable, if water is needed on a day where there is little to no wind, obviously the wind pump will not be able to pump water. This problem can be solved by a storage basin, as explained earlier. Many people who inhabit areas around wind turbines complain about the noise that is created by the rotation of the rotor, but this generally applies only too many wind turbines grouped together. As the rotors are improved upon and become more aerodynamic, the noise level will decrease greatly.

WIND POWER. As with most other alternative energy sources that were aggressively researched during the energy crisis of the early 1970s, the interest in wind power has waned considerably in recent years. A number of new design concepts were produced during the energy-awareness period and one day may receive considerable attention. Directly attributable to energy from the sun, the winds arise from atmospheric thermal differences.

The Macroscopic View. In reviewing the macroscopic availability of total wind energy available on the Earth, Gustavson (1979) starts with the solar flux at the Earth's distance from the sun — at a value of 1400 watts per square meter which, when averaged over the Earth's surface, amounts to a total intercepted flux of 1.8×10^{17} W (350 watts per square meter). This, then, is the upper limit on all solar-energy-based processes. A number of authorities essentially agree that only about 2% of this gross amount of solar energy reaching the Earth results in gross global wind energy. Thus, the gross wind energy for the Earth becomes 3.6×10^{15} W, an upper limit on the theoretical potential of wind energy technology. For utilization of wind energy in terms of concepts proposed to date, only the near-surface winds would be tapped. Ellsaesser (1969) estimated that 35% of total global wind energy is dissipated within one kilometer (0.62 mile) of the earth's surface. It was further estimated (Brunt, 1939) that about 90% of this 35% component is dissipated close to or essentially adjacent to the characteristically "rough" surface of the earth where there is interference with a smooth flow of wind currents. Applying the foregoing considerations, the near-earth wind energy available over the earth approximates 1.3×10^{15} W.

The atmosphere is a great heat engine fueled by the sun. As in all such engines, only a fraction of the energy supplied can be transformed into work. The remainder must be rejected from the system, in this case by the loss of heat by long wave radiation to space from the earth and its atmosphere. The winds and ocean currents represent the work done by the engine and may be thought of as its flywheel. The windmill or aerogenerator converts the motion of translation of the winds of this heat engine into a rotation capable of driving an alternator. Since the earth-atmosphere system itself disposes of the rejected heat, wind power systems do not have to contend with the waste heat that presents problems in other kinds of power plants.

Based upon estimates (Putnam, 1948), there is 20 times more potential for windpower than for water power. An estimate of the annual average wind power available over the continental United States and coastal waters is given in Fig. 1. The estimates for the mountainous western half of the country and for the Appalachians are subject to considerable uncertainty. This is true because the values given are based upon measurements of standard weather stations, usually located at or near airports, the locations of which are usually selected so as to avoid high winds. For example, the map shows the Columbia River Gorge area lying east of Portland, Oregon as having only 100 watts per square meter per year of wind power, although actual wind measurements in the gorge show clearly a power level several times greater than this. Shoreline winds along the Oregon coast are also stronger than shown.

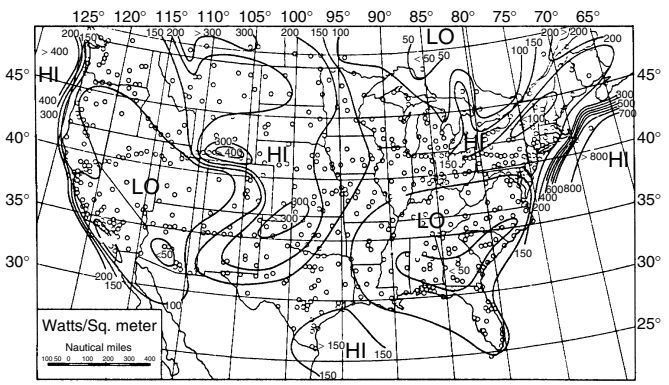

Fig. 1. Available wind power in the United States (annual average). Markings on contour lines are watts/square meter.

Importance of Wind Speed. A very significant factor pertaining to the Earth's winds as a source of electrical energy is that the power produced is proportional to the cube of wind speed. The result is readily derived from the kinetic energy of wind. The mass of air m with speed V and density r flowing per unit time through area A swept by the blades of a conventional horizontal-axis wind turbine is rAV. Thus, the kinetic energy of this mass of air is given by:

$$\text{Kinetic energy} = \tfrac{1}{2}\, mV^2 = \tfrac{1}{2}\rho AV^3$$

As shown from the theoretical analysis by Betz (1919), the maximum fraction of this kinetic energy that can be extracted from the wind is $\frac{16}{27}$ or 0.593. Thus, the theoretical maximum energy output of a wind turbine is given by:

$$\text{Theoretical maximum power output} = 0.297\ \rho A V^3$$

The process of energy conversion leads to power reductions that vary with the type of wind turbine and aerogenerator and which are roughly one-third of the theoretical maximum output. Hence:

$$\text{Available power output} = \left(\tfrac{2}{3}\right) 0.297\ \rho A V^3 \simeq 0.2\ \rho A V^3$$

If the diameter of the blades of the rotor system is D, then the foregoing equation becomes:

$$\text{Available power output} \simeq 0.05\ \pi \rho D^2 V^3$$

The power available for a given wind speed is thus proportional to the square of the rotor diameter. Additional quantities requiring definition are:

$$\text{Power coefficient, } C_p = \frac{\text{Power Output of Wind Turbine}}{\frac{1}{2}\rho A V^3}$$

$$\text{Overall power coefficient, } C_{op} = \frac{\text{Power Output at Generator}}{\frac{1}{2}\rho A V^3}$$

The coefficient, C_{op}, thus includes the inefficiencies of the transmission and generator.

The term *windmill* was used for centuries to describe an assembly of equipment used for extracting power from the wind. More modern terms include *wind turbine generators* and *aerogenerators*.

Since the power generated by the wind is proportional to the cube of the wind speed, it is obviously important to locate areas of persistently high winds. For example, a 10 meter/second (22 miles/hour) wind will produce 8 times as much power as a 5 meter/second (11 miles/hour) wind. Surveys to locate suitable wind power sites have been conducted in the United States, France, and Great Britain. Wind measurements, especially in rough terrain, must be taken with great care. Misreading of wind power potential has resulted in certain past failures of wind power systems. See also **Winds and Air Movement**.

Velocity and Power Duration Curves. The single most valuable piece of information that can be obtained about a potential wind power site is its power duration curve, which is conveniently obtained from its velocity duration curve, shown in Fig. 2. The horizontal axis gives the number of hours in the year (8,760) and the vertical axis is wind velocity. Thus, the graph gives the number of hours in the year during which the indicated wind velocity was exceeded. A power duration curve is similar because power is proportional to the cube of wind speed. See Fig. 3. The power duration curve thus gives the number of hours per year that the power output exceeds the indicated values, which are obtained in part by cubing the wind speed. This particular curve is for a site with relatively little time with low wind during the year. During the interval ge, the wind is too light to produce significant power. At the wind speed corresponding to g (say 3 meters/second or 7 miles/hour), appreciable power is being generated. The point fg is called the "cut-in" point. With higher wind speeds, the power output is greater and at c the aerogenerator is operating at its rated capacity. At greater wind speeds, the output is generally held constant at this value (for component cost optimization reasons with conventional components) for full-load operation by adjusting the pitch of the blades, or by some other method. At some much higher wind speed, b, called the "furling point," perhaps about 27 meters/second (60 miles/hour), it is advisable to shut down the plant to avoid damage.

In the diagram, the hatched area bcfgh under the power duration curve represents the actual annual output of energy to the same scale as the rectangle adeo represents the annual output if the plant were running at full-rated power throughout an entire year. The ratio of area bcfgh to area adeo is the annual plant load factor and multiplication of this by 8,760 gives the specific output in kilowatt hours per year per kilowatt. Thus, the specific output is the equivalent number of hours of full-load operation.

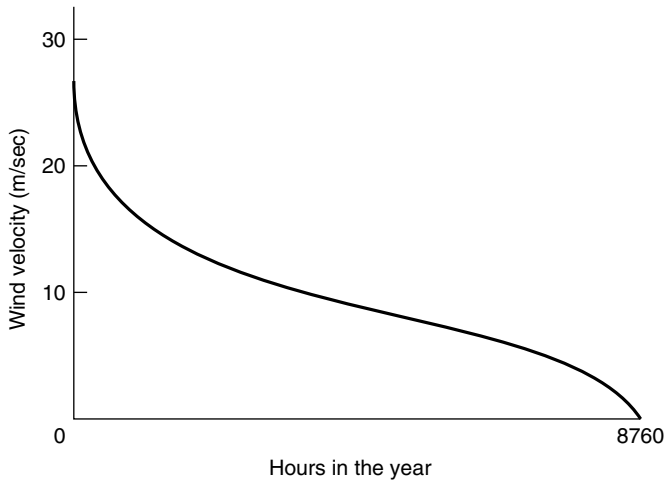

Fig. 2. Wind velocity-duration curve.

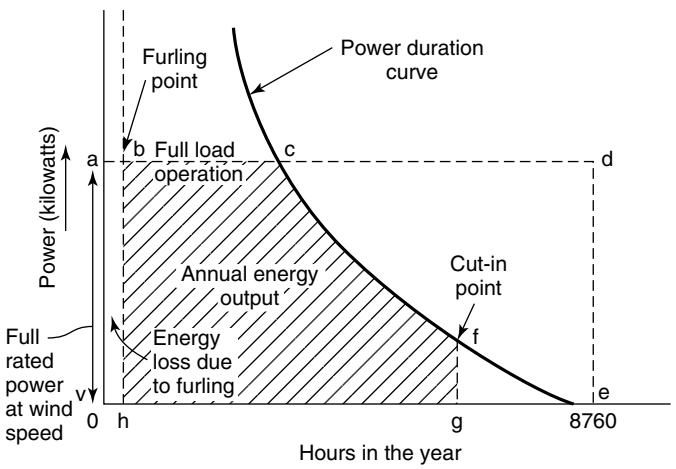

Fig. 3. Wind power-duration curve.

Milestones and Wind Power

It is estimated that wind power has been utilized by people for at least 15 centuries, but that more scientific and engineering information concerning the utilization of this source of power has been accumulated during the past few decades than during the early centuries. However, some fundamental principles have been known for at least a few hundred years, as reflected by the refinements of earlier designs (so-called Dutch windmills and the small windmills, estimated at over 6 million units, used at one time throughout the farmlands of North America and in other areas of the world). Wind power became essentially obsolete during most of the present century because of the convenience and relatively low cost of electric power, which was brought to the hinterlands via very ambitious programs of rural electrification. It was not until many countries slowly awakened to the prospects of energy shortages and high energy costs that wind power, as a component of solar power, created new interest.

Some progress did occur nevertheless during the second quarter of this century when wind power, in general, had descended almost to the status of a curiosity. For example, Darrieus, built an aerogenerator at Bourget, France in 1929 that had a tower 20 meters (66 feet) high, with blades of the same diameter. A direct-current generator rated at 0.015 megawatts at wind speed of 6 meters/second (13.4 miles/hour) was wind-powered. During the late 1950s, another, larger unit rated at 0.8 megawatt and for operation at higher wind speeds was also built in France.

A large aerogenerator was installed at Yalta (near the Black Sea) in the former U.S.S.R. in 1931. The tower was 23 meters (75 feet) high, with blades 30.5 meters (100 feet) in diameter were used. An alternating current generator (rating not precisely known) was designed for operation at 11 meters/second (24.6 miles/hour).

Fig. 4. Wind turbines arranged as a wind farm.

In 1920, in Germany, an aerogenerator designed by Kumme and consisting of six blades was built. This unit included a generator on the ground and a long, vertical, flexible shaft topped by a bevel gear to transmit torque to the ground. A bit later, an aerogenerator was proposed by Honnef of Berlin, but was not built. This design involved 5 wind turbines, each nearly 40 meters (250 feet) in diameter, supported on a single large tower, 305 meters (1000 feet) high. See Fig. 4. The inventor rated the potential capacity of his design at 50 megawatts. Also, in Germany, several aerogenerators were designed by U. Hütter (Univ. of Stuttgart), built and constructed during the early 1960s. Capacities up to 0.1 megawatt and fiberglass blades were part of the design. These machines were reported to have good operating characteristics and resistance to fatigue. There remains much interest in Hütter's concepts.

In Great Britain, an aerogenerator using a pneumatic transmission system and designed by French engineer, J. Andreau, was built in the mid-1950s for the Enfield Cables organization. The tower was 30 meters (100 feet) high; the blades were 24 meters (80 feet) in diameter; and the unit had a rated capacity of 0.1 megawatt at 13.4 meters/second (30 miles/hours). The unit operated successfully for a number of years in Algeria.

In Denmark, during World War II, a total of 18 aerogenerators were constructed in the 70 to 90 kilowatt range. These supplied direct-current power to the dc power grids. Another aerogenerator, designed to produce 0.2 megawatt at speed of 15 meters/second (34 miles/hour) was constructed at Gedser. For this unit, the tower was 26 meters (85 feet) high; the blades (3 in number) were 24 meters (79) feet in diameter; and the electric generator located on a horizontally rotating platform atop the tower produced 380 volts ac. Although the unit was shut down in 1968, it was still standing as of the mid-1970s.

In the United States, the largest wind turbine ever built, as of that time, was the often-cited Smith-Putman generator, located on Grandpa's Knob near Rutland, Vermont. It was built in the 1940s and was in operation over test-run intervals in the period 1941–1945, after which it was continuously operated as a routine generating station on the lines of Central Vermont Public Service Corporation. It was ultimately shut down because of loss of a blade.

In 1974, the National Aeronautics and Space Administration (NASA) constructed an experimental wind turbine generator near Sandusky, Ohio. The tower was 30 meters (100 ft) high; the rotor was 38 meters (125 ft) in diameter. Planned output was 100 kW at 460 V, 3-phase, 60 Hz alternating current. Before being shut down, the unit gained considerable experience in designing and operating large aerogenerators.

Early in the revived interest in aerogenerators during the 1970s in the United States, ERDA (Energy Research and Development Administration) concentrated its attention on larger machines. However, in mid-1976, a program was established at the Rocky Flats laboratory (near Denver, Colorado) to evaluate the performance of many types of small wind machines. As pointed out at the time, whereas the large-wind-machine program is one of sequential development, the small-scale program is intended to emphasize parallel development of competing machines. Also, later in the 1970s, U.S. energy officials expressed an increasing interest in the wind-farm concept which involves lower-capacity machines.

Wind Power for Cargo Ships. Also, during the energy crisis period of the 1970s, much interest had been developed in wind-powered ships. Japan, Germany, and the United States researched the potentials of wind energy and a few experimental craft were built. There had been a lull in sailing craft research, except for pleasure vessels, since the very early 1900s. The final demise of large sailing ships is marked by some authorities as occurring at the end of World War I. They were forced into retirement by the advantages of low-cost fossil fuels in providing steady power that improved the reliability of scheduling arrivals and departures. Authorities estimated that between 20 and 30% of the operating costs of modern powered vessels goes into fuel. The some 25,000 commercial vessels of more than 1000 deadweight tons used worldwide in international trade consume between 5 and 8% of the total oil consumption in the world (communist countries excepted). Sail power is not only attractive from the standpoint of fuel savings, but also because the energy source is constantly renewable and provokes no significant environmental problems. It has been estimated (Bergeson, 1979) that a reduction of 10–20% in consumption of bunker oil by ships could reduce cargo transportation costs (1979 $) by as much as $5.5 billion per year. Another factor favorable to wind power for ships is the large bank of knowledge in this area. As of the early 1900s, sailing ships had been brought to an advanced state of development — and this knowledge is retrievable. To this is added prior experience, which has greatly enhanced the technology of land-based wind machines. Wind-powered ships of the future also can take advantage of advances in materials (as for sails), of hull antifouling chemicals, of auxiliary electrical, mechanical, and control equipment — not to mention major improvements in weather forecasting and ship-to-shore communications, which can be invaluable in plotting the most wind-efficient courses to follow.

Much pioneering research of the recent period in sailing ship technology was carried out at the Institut für Schiffbau in Hamburg, Germany. In wind tunnels and towing tanks, the performance of various hull configurations,

including 1902 as well as recently designed hulls (as designed by Wilhelm Prölss of the Institute) were tested. As pointed out by Bergeson (1979), speed was measured at various angles of course with varying wind velocities and sea states, and actual log book data for the 1902 rig were correlated with the tank and wind tunnel test data. As a result, the propulsive force of the 1902 vessel was improved twofold. Further, the mean voyage speed was increased by 58% under sail alone, and up to 82% with the use of modest auxiliary power during part of the voyage time. Polar diagrams, which show ship speed under varying wind velocities, sea states, and headings, clearly summarized the gains in performance. In 1974, the U.S. Maritime Administration funded a study at the University of Michigan on the "Feasibility of Sailing Ships for the American Merchant Marine." Using information obtained from the German research and assuming a modern square rig of the same aerodynamic configuration as that designed by Prölss, the project postulated performance characteristics and made estimates of construction and operating costs of cargo sailing ships of 15,000, 30,000, and 45,000 deadweight tons. The report found no technical barriers to the development of such ships.

There are several schools of thought as regard the rigging (or arrangement of wind collectors) to be used on future wind-powered cargo vessels. Naval architects and marine engineers have looked back nearly a century or more to the most successful of the sailing ships whether they be square-rigged or of schooner configurations. Even in borrowing from older, tested designs, taking modern technology into consideration, the new designs are strikingly different. In some designs, rotating masts, fully equipped with sensors and automatic controls have been envisioned. See Fig. 5. Some authorities have a preference for a catamaran design. For example, Bergeson (1979) gives three advantages of a catamaran: (1) about half of the cargo of a catamaran can be considered as highly effective ballast — operating on a huge lever arm equal in length to the distance between the hull centerlines and thus creating enormous righting moment and impressive sail-carrying ability, as compared with the craft's low hull resistance, which results in impressive speeds for these craft; (2) when beached, a catamaran gains immense stability with both bows grounded, whereas a trimaran, for example, can lurch violently, creating large shock loads; and (3) the catamaran is safer and more practical in larger sizes designed to carry heavy cargoes and water ballast. Bergeson envisions that a catamaran might be about 67 meters (220 feet) long with a deadweight capacity equivalent to that of 54-meter (180-foot) single-hull design. It is envisioned that such a catamaran with a light load would have a maximum potential speed of 25 knots in winds of 25 to 30 knots. Probably over the course of a year, the catamaran would achieve an average speed in excess of 12 knots.

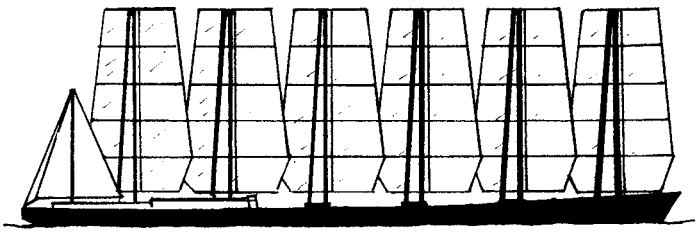

Fig. 5. Bulk cargo sailing ship of 45,000 deadweight tons. This design resulted from University of Michigan study. Tripod masts were used instead of rotating masts as used in the earlier *Dynaship* designed by Pröiss of Germany. Rotating masts can be used to set sails at most effective angle. In the tripod design, sails are trimmed by mechanically "bracing" the yards about a pivot on the leading side of the mast. Furling or unfurling sails is accomplished by rotating a vertical rod (jack stay) set between the yards and forward of the mast. (*After Bergesson*.)

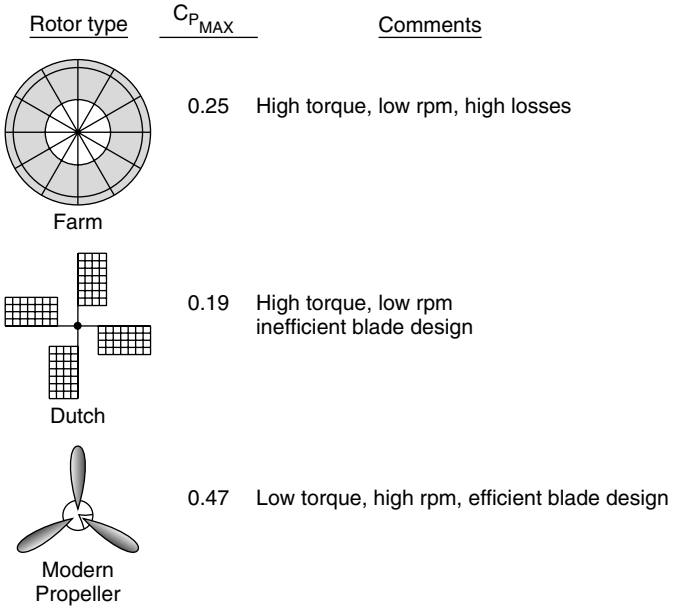

Fig. 6. Power extractable from three types of horizontal-axis rotors. (*From Savino*.)

Aerogenerator Configurations

Horizontal-Axis Rotors. Three well-established types are shown in Fig. 6. The modern propeller when used in a wind turbine utilizes variable-pitch in order to regulate rate of shaft rotation to achieve maximum efficiency. Other types include the flexible sailwing rotor and a design consisting of a circular array of 48 thin and narrow blades stressed in tension by a surrounding circular hoop, which serves as a rim drive to rotate at high speed and without step-up gearing the shaft of a generator. Various factors that cause dynamic loading of the rotors are shown in Fig. 7. The blades are attached to the hub in a flexible manner, permitting them to move to and fro in the direction of the wind in a vibration mode known as *flapping*. As a group, the blades of the horizontal-axis rotors are driven by lifting action. As a result, the speed ratio (ratio of blade tip speed to wind speed) is high, reaching a value as large as 12. The efficiency of a wind turbine at these large speed ratios is high.

Vertical-Axis Rotors. The best known vertical-axis rotor is made up of two identical hemicylinders with their axes vertical. The patterns of air flow around and air pressure on two such hemicylinders are shown in Fig. 8. As described by Klemin (1925), when the configuration is as shown in Fig. 8(a), there is a reduced pressure behind hemicylinder a as it moves against the wind, reducing the torque. If, however, there is an air passage between the hemicylinders, as in Fig. 8(b), the air pressure behind hemicylinder a is increased rather than reduced, with the result that the torque is about three times greater than without the air passage. This vertical-axis rotor was developed by the Finnish engineer Savonius (1931) and is being used increasingly for small wind-power installations.

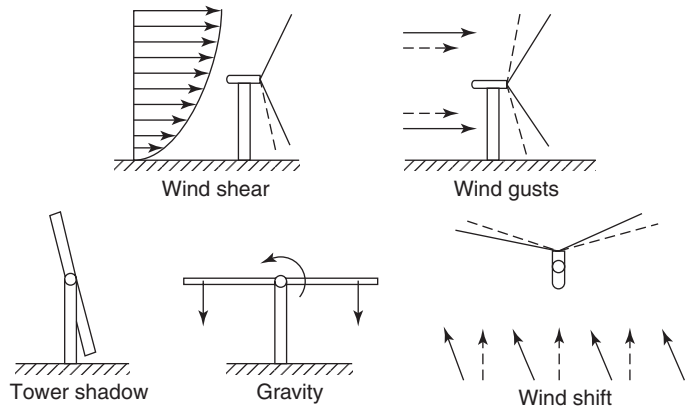

Fig. 7. Various factors that cause dynamic loading of rotors.

The French engineer, Darrieus (1931), designed another type of vertical-axis rotor, a modern version (developed by South and Rangi, 1971 and 1972) of which is shown in Fig. 9. The flexible metal strips take the form of a catenary and act in a lifting mode as they rotate so that, for a given wind speed, the unit rotates more rapidly and is more efficient than the Savonius rotor. Unfortunately, the Darrieus rotor is not self-starting even in high winds.

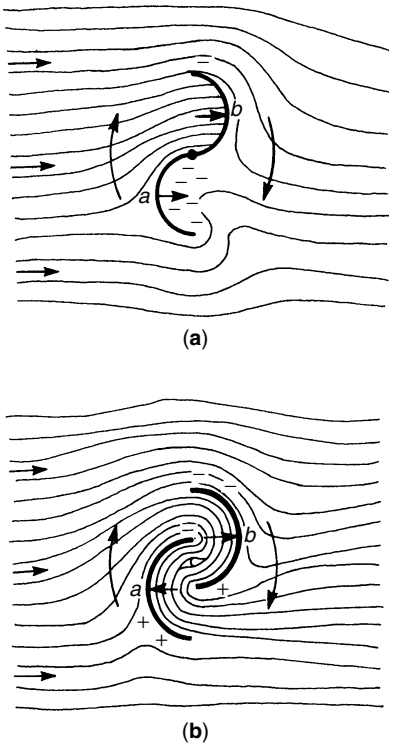

Fig. 8. Patterns of air flow around and air pressure on hemicylinders. (**a**) Reduced pressure behind hemicylinder as it moves against the wind; (**b**) air passage between hemicylinders increases pressure behind hemicylinder with the result that torque is about three times greater than without air passage.

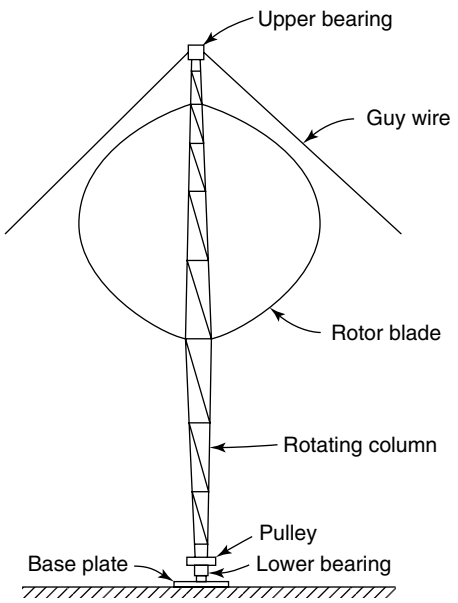

Fig. 9. Vertical-axis rotor developed by South and Rangi.

The performance characteristics of various rotor configurations (according to Wilson and Lissaman, 1974) are shown in Fig. 10. This analysis suggests that the two-blade type is the most efficient type now available. Other studies (General Electric, 1975) and Kaman Aerospace (1975) reached the same conclusion.

Transmissions. The rate of rotation of large wind turbine generators operating at their rated capacity can be controlled by varying the pitch of the rotor blades. Because optimum generator output requires much greater rates of rotation (about 1800 revolutions per minute), it is necessary to increase greatly the lower rotor rate of turning. Among transmission options are mechanical systems involving fixed ratio gears,

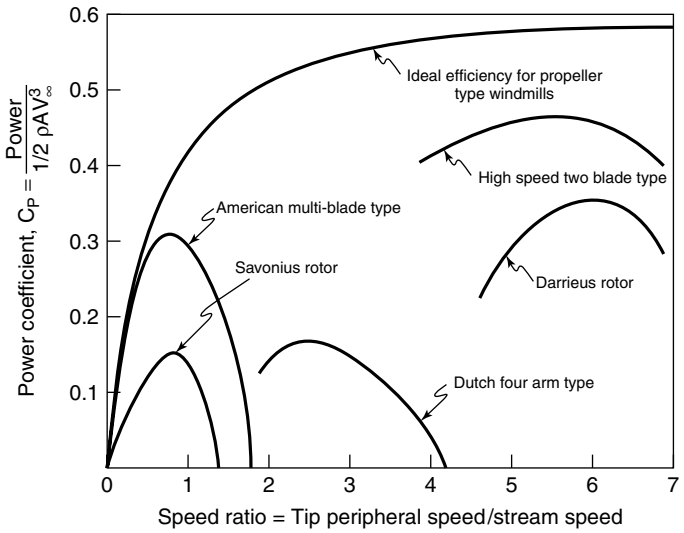

Fig. 10. Performance characteristics of various rotor configurations.

belts, and chains singly or in combination; or hydraulic systems involving fluid pumps and motors. Fixed-ratio gears are often preferred for top-mounted equipment because of their high efficiency and low system risk. For bottom-mounted equipment, which requires a right-angle drive, transmission costs can be reduced substantially by using large-diameter bearings with a ring gear mounted on the hub to serve as a transmission to increase rotor speed to generator speed. This approach has considerable flexibility.

Generators. Either constant- or variable-speed generators may be used, by variable-speed units are costly. Among constant-speed generator options are synchronous, induction, and permanent-magnet units. Like other components of aerogenerator systems, the transmission and generator technology is subject to continuing research and improvement.

Preferred Site Characteristics. Considerable attention has been given to those factors which effect aerogenerator capacity and efficiency. These are well summarized by Savino (1974): (1) a site should have a high annual wind speed; (2) there should be no tall obstructions for a mile or two upwind; (3) the top of a smooth, well-rounded hill with gentle slope lying on a flat plain or a site located on an island in a lake or sea is usually an excellent site; (4) an open plain or an open shoreline may be a good location; (5) a mountain gap which produces wind funneling is good. Some of these conditions are shown in diagrams of Fig. 11.

Ecological signs of a good wind site include: (1) flagging of trees, in which the branches stream downwind, as frequently found along shorelines where there is a prevailing on-shore wind; (2) throwing of trees, in which the main trunk is permanently bent downwind; (3) wind clipping, which causes abnormally low trees with tops of uniform height; (4) tree or bush carpets, in which vegetation never grows taller than a low scrubby bush. Mountainous coastal terrain provides some of the very best wind-power sites.

Aerogenerator Farms. The wind is a low density source of power compared with water. For instance, the energy developed is the product of the density of the air and the cube of wind speed. The density of air near sea level is about one-thousandth that of water — thus about 1,000 times more air than water must pass through a turbine at the same speed to generate equal amounts of power. This means that wind turbines must be larger than water turbines to achieve equal power output.

If wind power is to be considered as more than a source of electrical energy for isolated homes and farms, it becomes apparent that arrays or "farms" of wind turbines will be needed to generate enough power to justify feeding it into existing networks. A small farm consisting of 16 vertical rotor units of the Savonius type is shown in Fig. 12. The units are supported in a vertical position by an inexpensive system of guy wires. The only compression members are the vertical shafts of the rotors which are stiffened by the two hemicylinders of the Savonius rotors.

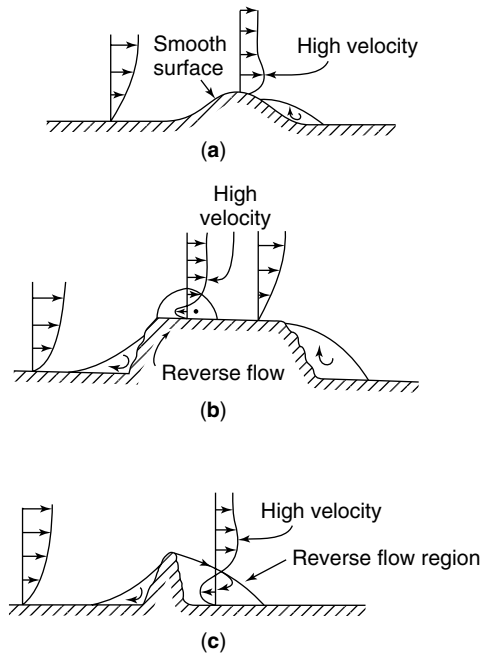

Fig. 11. Factors affecting wind-power locations: (**a**) well-rounded hill or ridge makes a favorable site; (**b**) hill or ridge with abrupt sides makes an unfavorable site; (**c**) sharp peak may possibly be suitable.

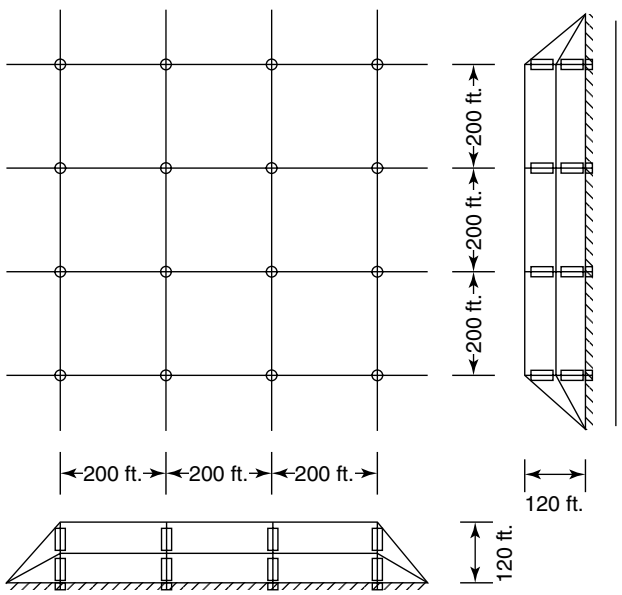

Fig. 12. Layout of small aerogenerator farm. (Note: 120 feet = 36 meters; 200 feet = 61 meters.)

Wind Energy Storage. This is a problem common to most solar energy systems. A logical possibility is pump storage of water, similar to that currently used in conventional hydroelectric power plants. The use of wind to compress air and store it in caverns or preferably aquifiers has been studied. The use of a very strong flywheel made up of radially oriented rods of high tensile strength has been explored by Rabenhorst. Other possibilities include use of the generated electricity to produce hydrogen and possibly other fuels.

WINDS-ALOFT OBSERVATION. See **Meteorology**.

WINDS AND AIR MOVEMENT. Air motion relative to the surface of the Earth is termed wind. Since only slight horizontal variations in the density of the air can occur ordinarily, and the total volume of the atmosphere is substantially constant, it is evident that a wind is necessarily a circulation of the atmosphere, i.e., any movement of the air in one direction must be offset by a return current elsewhere. All such movements are the result of thermal energy due to the heat of the Sun.

Although the winds are caused primarily by differences of temperature, they are more directly related to differences of atmospheric pressure, through the continuous interaction of meteorological highs and lows. Further, circulatory modification comes from the rotation of the earth, surface friction, frontal movements, and ground surface characteristics.

Where averaged over long periods, local and small-scale irregularities in the motions of the atmosphere disappear, and a generalized pattern of winds is manifest. There are five generalized latitudinal wind belts in each hemisphere, which correspond to the four latitudinal pressure belts in each hemisphere: (1) the equatorial trough, or doldrums, is a narrow low pressure belt extending north and south from the equator, where winds are light and variable, and where frequent calms occur; (2) the trade wind belt, with winds remarkably constant in both direction and velocity, extends from the doldrum belt to (3) a narrow high-pressure belt of calm air movement at about 30° or 35°, known as the horse latitudes; (4) from the horse latitudes and extending toward the poles to 60° or 70° north and south are the westerlies, highly variable winds in both velocity and direction; and (5) at 60° or 70° is a narrow low-pressure belt known as the subpolar low; between this and the high-pressure belt at the 90° pole (the polar highs) blow the cold, sometimes violent winds of the polar easterlies. See Figs. 1 and 2.

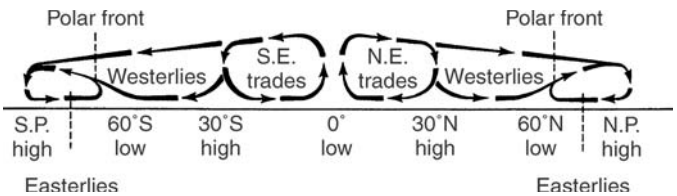

Fig. 1. Vertical cross section through the troposphere from the equator to the poles, showing air movements at and above the Earth's surface.

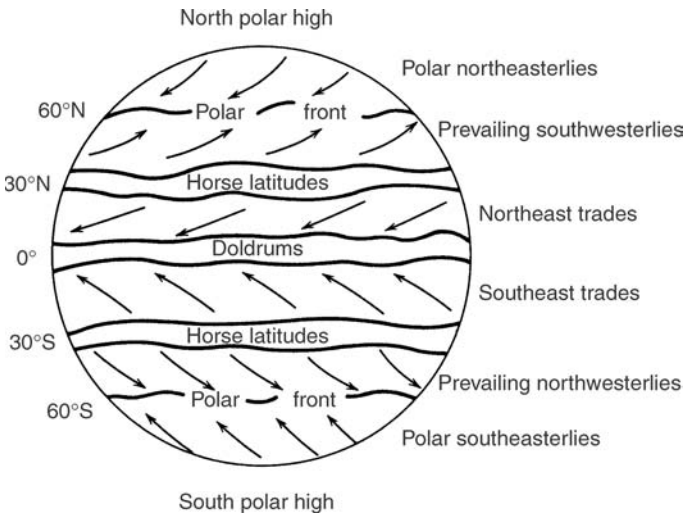

Fig. 2. Generalized map of the pressure and wind belts of the Earth.

Because pressure decreases more rapidly with altitude when air is cold, surface-wind characteristics disappear slowly with altitude; and at considerable height, the circulation is generally westerly.

Two well-developed, semi-permanent cyclones are present in the Northern Hemisphere, one located over the North Atlantic near Iceland, known as the Icelandic Low, and the other in the Aleutian area of Alaska, known as the Aleutian Low. In the Southern Hemisphere, there is a more-or-less continuous belt of low pressure at the corresponding latitude. There is considerable change in the general circulation of the atmosphere from winter to summer, the effects of which are known as monsoon effects. Another major seasonal change is the migration of the equatorial and subtropical circulations (doldrums, horse latitudes, and trade winds) north and south with the sun. This causes weakening of the westerlies during summer and strengthening during winter; weakening of the Icelandic and Aleutian lows during summer and weakening of the polar circulations in summer.

The winds may be roughly classified into three types: (1) winds that are, in a sense, permanent, including the easterly trade winds of the tropics, and the westerlies prevailing in the temperate zones; (2) seasonal winds, such as the monsoons and the smaller scale diurnal mountain and valley winds, and land and sea breezes; and (3) local winds and storms, which temporarily interrupt the more general air movements prevailing at the time. Among these are the great cyclones and anticyclones characteristic of North American climate, ocean cyclones (including hurricanes or typhoons), thunderstorms, tornadoes, waterspouts (or ocean tornadoes), foehns (chinooks), and the cold fall winds, mistrals, and blizzards.

Winds may also be classified by their origin and movement:

1. **Gradient winds** — any horizontal wind velocity tangent to the contour line of a constant-pressure surface (or to the isobar of a geopotential surface) at the point in question. At such points where the wind is gradient, the Coriolis acceleration and the centripetal acceleration together exactly balance the horizontal pressure force:

$$\frac{V_{gr}}{R} + fV_{gr} = -g\frac{\partial z}{\partial n},$$

where V_{gr} is the gradient wind speed, R the radius of curvature of the path, f the Coriolis parameter, g the acceleration of gravity, z the elevation of the constant-pressure surface, and n the direction normal to the streamline and contour toward decreasing elevation, that is, to the left of the direction of flow in the Northern Hemisphere and to the right in the Southern Hemisphere. Since $R > 0$ for cyclonic flow and $R < 0$ for anticyclonic flow, it follows that the cyclonic gradient speed is less than (and the anticyclonic gradient speed is greater than) the geostrophic wind speed for the same latitude and pressure force.

Cyclonic winds blow counterclockwise about regions of relatively low pressure in the Northern Hemisphere and clockwise in the Southern Hemisphere. *Anticyclonic winds* blow clockwise about regions of relatively high pressure in the Northern Hemisphere and counterclockwise in the Southern Hemisphere.

2. **Geostrophic winds** — that horizontal wind velocity for which the Coriolis acceleration exactly balances the horizontal pressure force:

$$f\mathbf{k} \times \mathbf{v}_g = -g\nabla_p z,$$

where $\mathbf{v}_g$ is the geostrophic wind, f the Coriolis parameter, $\mathbf{k}$ the vertical unit vector, g the acceleration of gravity, ∇_p the horizontal del operator with pressure as the vertical coordinate, and z the height of the constant-pressure surface. The geostrophic wind is thus directed along the contour lines on a constant-pressure surface (or along the isobars in a geopotential surface) with low elevations (or low pressure) to the left in the Northern Hemisphere and to the right in the Southern Hemisphere. The speed of the geostrophic wind V_g is given by

$$V_g = -\frac{g}{f}\frac{\partial z}{\partial n},$$

where $\partial z/\partial n$ is the slope of the isobaric surface normal to the contour lines to the left of the direction of motion in the Northern Hemisphere and to the right in the Southern Hemisphere. The geostrophic wind is defined at every point except along the equator. The validity of this approximation in dynamic theory depends upon the particular context.

3. **Cyclostrophic winds** — that horizontal wind velocity for which the centripetal acceleration exactly balances the horizontal pressure force:

$$\frac{V_c^2}{R} = -\alpha\frac{\partial p}{\partial n},$$

where V_c is the cyclostrophic wind speed, R the radius of curvature of the path, α the specific volume, p the pressure, and n the direction normal to the streamlines toward the center of curvature of the path. The cyclostrophic wind can be an approximation to the real wind in the atmosphere only near the equator, where the Coriolis acceleration is small; or in cases of very great wind speed and curvature of the path (such as a tornado or hurricane), so that the centripetal acceleration is the dominant one.

4. **Antitriptic winds**, of small scale and short durations, blow, in general, along the pressure gradient. *Heliotropic winds*, land and sea breezes, and mountain winds, are of this type.
5. The narrow jet stream moves at high speed in an irregular easterly course through the upper air of the Temperate Zone.

Wind velocity increases, on the average, with altitude in the upper troposphere and decreases in the lower stratosphere. At higher elevations in the stratosphere, conditions of absolute calm may vary with wind velocities of 250 miles (402 kilometers) per hour. Winds-aloft observations, which determine such conditions, are commonly made by means of small pilot balloons, carrying radiosondes (see also **Weather Technology**). Winds of high velocity, changing in direction according to season, have been observed at heights of nearly 100 miles (161 kilometers).

Wind Equations. Many factors influence the movement of air in any quasi-horizontal plane at or above the surface of the Earth. In the friction layer, frictional forces play an important role. Convergence and divergence also play their part in determining air flow. Isallobaric fields have some influence. But, in general, three major forces play the main roles in establishing the winds. They are:

1. The Coriolis or deflective force due to the Earth's rotation, which is given by $2\omega V \rho \sin \phi$.
2. The pressure gradient of the atmosphere, which is given by dp/dx.
3. Centrifugal force due to curvature of path of air parcel, which is given by V^2/ρ.

If air movement is unaccelerated, these three forces are the only factors involved in determining the wind. When other forces are active, accelerations and decelerations alter equilibrium conditions among the three principal forces. However, equilibrium conditions hold, except under

the excessive influence of one or more of the minor forces, and winds are generally determined by the balance among the three main forces.

There are several cases possible for establishing a balance of forces among the three. The following are for the Northern Hemisphere.

Case 1. If the parcel of air is moving in a field of pressure that is higher at the center of the field than at the exterior, the pressure gradient is directed outward from the center. In this case, the flow is clockwise and the defective or Coriolis force balances the pressure gradient and the centrifugal force:

$$\frac{dp}{dx} + \frac{V^2\rho}{r} = 2\omega\rho V\sin\phi$$

$$\begin{pmatrix}\text{pressure}\\ \text{gradient}\end{pmatrix}\begin{pmatrix}\text{centrifugal}\\ \text{force}\end{pmatrix}\begin{pmatrix}\text{coriolis}\\ \text{force}\end{pmatrix}$$

where

dp/dx = pressure gradient
V = velocity of the parcel
ρ (rho) = density of the air
ω (omega) = angular velocity of the earth
r = radius of curvature of the percel's path
ϕ (phi) = latitude

Solving this equation, we obtain

$$V = r\omega\sin\phi \pm \sqrt{(r\omega\sin\phi)^2 - \frac{r}{\rho}\frac{dp}{dx}}$$

But $V = 0$ when $(dp/dx) = 0$, and we have

$$V = r\omega\sin\phi - \sqrt{(r\omega\sin\phi)^2} - \frac{r}{\rho}\frac{dp}{dx}$$

It is not possible to give meaning in this case to a negative value for the radical; therefore, the quantity under the radical must always be positive. This places a limiting value in wind velocity in a clockwise or anticyclonic system of winds, which is given by the value of zero for the quantity under the radical. We then have

$$V_{\max} = r\omega\sin\phi$$

For a given latitude, the quantity $\omega \sin \phi$ becomes fixed and $V_{\max}; /r$ is constant. At the equator, the quantity (sin ϕ) becomes zero and the velocity also becomes zero. Anticyclonic winds at the equator, therefore, are not possible.

For a given pressure gradient, the velocity of an anticyclonic wind increases toward the center of the system until the critical value of velocity is reached.

Case 2. If the parcel of air is moving in a field of pressure such that the pressure is less at the center than the exterior, the pressure gradient is directed inward toward the center. In this case, the flow is counterclockwise and the pressure gradient balances the deflective force and the centrifugal force:

$$\frac{dp}{dx} + \frac{V^2\rho}{r} + 2\omega\rho V\sin\phi$$

The solution to this equation is

$$V\pm = \sqrt{(r\omega\sin\phi)^2 + \frac{r}{\rho}\frac{dp}{dx}} - r\omega\sin\phi$$

Again, when $(dp/dx) = 0$, $V = 0$ and the + sign before the radical is necessary:

$$V = \sqrt{(r\omega\sin\phi)^2 + \frac{r}{\rho} - \frac{dp}{dx}} - r\omega\sin\phi$$

The quantity under the radical is always positive, so there can be no limiting value on the velocity. At the equator, where sin; ϕ is zero, the pressure gradient is still present under the radical to give the velocity a positive value. Winds blowing under these conditions are known as cyclonic winds and include both tropical cyclones and wave cyclones as the main types.

Case 3. If the flow of air is in a straight line, the centrifugal-force term drops out and the balance of forces is between the pressure gradient and the deflective force only:

$$\frac{dp}{dx} = 2\omega\rho V\sin\phi$$

$$V = \frac{dp/dx}{2\omega\rho V\sin\phi}$$

This wind is known as the geostrophic wind in contrast to Cases 1 and 2, which are gradient wind cases. Geostrophic winds increase southward for a given pressure gradient and, theoretically, become infinitely great at the equator, where the denominator becomes zero. They are directly proportional to the pressure gradient at any given latitude.

Case 4. At the equator, where the deflective force drops out entirely, a balance between the pressure gradient and centrifugal force is possible:

$$\frac{\rho V^2}{r} = \frac{dp}{dx}$$

$$V = \sqrt{\frac{r}{p}\frac{dp}{dx}}$$

Winds of this type are cyclostrophic winds and blow cyclonically or counterclockwise about a center of low pressure. Hurricanes are the best example of cyclostrophic winds, and even though they develop and migrate from the equatorial zone, the deflective force plays no significant role until the center is considerably removed from low latitudes.

In the Southern Hemisphere, wind relations are the mirror image of the Northern Hemisphere, i.e., they blow counterclockwise about centers of high pressure, clockwise about centers of low pressure, and with high pressure to the left.

Specific Winds and Wind-Related Terms

Afghanets. Strong gusty winds, that occur on the upper course of the Amu Darya (river) in Turkmenistan (i.e., coming from Afghanistan). It is preceded and accompanied by duststorms.

Almwind. Local name for a foehn that blows from the south (Hungary) across the Tatra Mountains south of Krakow, Poland, and descends the northern valleys; similar to the Alpine south foehn. See **Foehn**. It is sometimes stormy and may reach 20–25 m s^{-1} (40–50 mph) in gusts, especially in spring and fall. It raises temperatures to as much as 14 °C (57.2 °F) above the normal for the season, and in winter and spring it causes avalanches. At Zakopane (in southern Poland) it sometimes blows as a high foehn. This wind occurs in front of depressions moving eastward in the Baltic.

Along-slope Wind Systems. Thermally forced winds that blow up or down the sidewall slopes in a mountain valley, and the accompanying countercurrents when present; the slope-wind components of the mountain–valley wind system. During the daytime this system consists of upslope (anabatic) flow adjacent to the slope and often a compensatory return current directed downslope just above the upslope layer. At night it is a downslope (katabatic) flow layer near the slope, sometimes with a return flow aloft.

Along-valley Wind Systems. Thermally forced winds blowing along the main (longitudinal) axis of a valley, sometimes accompanied by countercurrents aloft; the up- and down-valley components of the mountain–valley wind systems. During the daytime, this system comprises an up-valley wind and its countercurrent if present. At night it is a down-valley wind and return flow if present.

Along-valley Winds. The component of topographically generated winds that are parallel to the valley axis and can occur during conditions of light or calm synoptic-scale winds such as those near the center of anticyclones. At night, cold, dense air flowing down the river valley from the higher elevations is called a *mountain wind* or *drainage wind* with typical depths of 10 to 400 meters (33 to 1,312 feet) and speeds of 1

to 8 m s^{-1}, while the weaker return circulation aloft is called an anti-mountain wind. During the day, the gentle up-valley flow of warm air along the valley floor is called a *valley wind*, and the return circulation aloft is called an *anti-valley wind*.

Anabatic Wind. In mountain meteorology, an upslope wind, driven by heating (usually daytime insolation) at the slope surface under fair-weather conditions. The mechanism of the anabatic wind can be described as follows. The warm surface heats a vertical column of the atmosphere starting at the slope surface and reaching up to a few hundred meters deep. This column is warmer than the column at the same levels over the valley or plain, resulting in hydrostatic low pressure over the slope relative to over the valley or plain. The horizontal pressure gradient, maximized at the slope surface, drives an acceleration directed toward the slope, or up the slope. Although the pressure-gradient forcing is at its maximum at the slope, surface friction causes the peak in the anabatic wind speeds to occur above the surface, often by several tens of meters; if the surface heating is strong, however, the momentum will tend to be vertically mixed. Speeds in the mountain–valley anabatic flow layer are often 3–5 m s^{-1}. Because heating at the surface promotes deeper mixing than cooling does, the heated layer, often occurring as a convective or mixed layer, is generally deeper than a cooled or katabatic layer. Slopes occur on many scales, and consequently anabatic flows also occur on many scales. At local scales anabatic winds are an along-slope component of mountain–valley wind systems. At scales ranging from the slopes of individual hills and mountains to the slopes of mountain ranges and massifs, anabatic flows represent the daytime component of mountain–plains wind systems. In general usage, this term does not suffer from the multiplicity of meanings that katabatic wind does. See also **Katabatic Wind**.

Anemometer. The general name for instruments designed to measure either total wind speed or the speed of one or more linear components of the wind vector. These instruments may be classified according to the transducer employed; those commonly used in meteorology include the cup, propeller, Pitot-tube, hot-wire or hot-film, and sonic anemometers

Antitrade Winds (or Antitrades). A deep layer of westerly winds frequently present above the surface trade winds of the tropics. They comprise the equatorward side of the mid-latitude westerlies but are found at upper levels rather than at the surface. The antitrades are best developed in the winter hemisphere and above the eastern extremities of the subtropical highs. Farther west their base is higher and their appearance less regular. The antitrades were formerly regarded as return currents carrying away, to higher latitudes, the air that rises in the intertropical convergence zones, the westerly component being due to the conservation of angular momentum as the air moves into higher latitudes. Bjerknes [1935] showed that this explanation is incomplete: The antitrades are dynamical in origin, and constitute an essential part of the atmosphere's primary circulation.

Athos Fall Wind. A cold, northeasterly, often strong fall wind descending the southerly slopes of Mount Athos, on the Hagion Oros Peninsula in northeastern Greece, and extending several kilometers out over the northern Aegean Sea.

Autan. (Also called *altanus*.) A strong southeast wind in south-central France, especially in Gascony and the upper Garonne River. Near the Pyrenees the autan is very turbulent, growing in strength in the valleys. At Toulouse its average speed is 13 m s^{-1} (30 mph) with gusts of 20–22 m s^{-1} (45–50 mph); it tends to be strongest at midday. It increases in speed up to a height of 450 meters (1,500 feet), above which it weakens and veers to the south. North of Toulouse it loses its special character and becomes an ordinary southeast wind. There are two types. 1) The autan blanc brings fine dry weather, cold in winter, hot in summer, as a result of the downslope motion imposed by the Pyrenees and southern Cevennes. It occurs with an anticyclone centered near Denmark or moving northeastward from the Azores. It lasts for two to four days in winter, but may persist for more than a week in summer, bringing severe drought and desiccating the vegetation; in Catalonia (northeastern Spain) a similar wind is called the outo. 2) The autan noir is less frequent and rarely lasts for more than two days; it is more humid and cloudy, bringing fog, rain, or snow over high ground near the sea. As such, it is more like the marin, the name applied to the southeast wind out of the Cevennes where its maritime character predominates.

Avalanche Wind. The rush of air produced in front of an avalanche of dry snow or in front of a landslide. The most destructive form, the avalanche blast, occurs when an avalanche is stopped abruptly, as in the case of an almost vertical fall into a valley floor. Such blasts may have very erratic behavior, leveling one house without damaging its neighbor. See also **Avalanche (Geology)**.

Ayalas. A warm and violently squally southeast wind in the center of the Massif Central of France. In spring it causes rapid melting of the snow, and in autumn it brings heavy rain; both cause flooding of the rivers. See **Marin**.

Backing. 1. According to general internationally accepted usage, a change in wind direction in a counterclockwise sense (e.g., south to southeast to east) in either hemisphere of the earth; the opposite of veering. 2. According to widespread usage among U.S. meteorologists, a change in wind direction in a counterclockwise sense in the Northern Hemisphere, clockwise in the Southern Hemisphere; the opposite of veering.

Beam Swinging. A technique used by wind profilers to determine the vertical profile of the wind vector above the radar by measuring the line-of-sight component of the wind sequentially along each of several different beam directions. The different beam directions can be obtained in various ways: 1) mechanically steering a single fixed-beam antenna; 2) electronically or mechanically steering the beam of a single fixed-position antenna; or 3) switching between multiple fixed-beam antennas.

Three beam positions can be used to determine the wind vector if it is assumed that the wind field is the same along those beams. At least five beam positions must be used to measure both the wind and its divergence. Wind profilers typically use one vertical beam and oblique beams that are between 10° and 25° off vertical. Oblique angles closer to the zenith make separation of horizontal and vertical wind components difficult and larger zenith angles make it less likely that the wind is uniform over the horizontal distances between beams. Large zenith angles also increase the radial range to the scattering volume at a given altitude, thereby reducing the strength of the returned signal.

Beam Wind. Nautical term for a crosswind, especially a wind blowing 90° from a ship's heading.

Beaufort Wind Scale. System of estimating and reporting wind speeds, invented in the early nineteenth century by Admiral Beaufort of the British Navy. It was originally based on the effects of various wind speeds on the amount of canvas that a full-rigged frigate of the period could carry, but has since been modified and modernized. See accompanying table. In its present form, for international meteorological use, it equates (a) Beaufort force, i.e., a number denoting the wind speed according to the Beaufort wind scale; (b) wind speed; (c) descriptive term; and (d) visible effects upon land objects or sea surface. See Table 1.

TABLE 1. BEAUFORT WIND SCALE

Code Number	Description	Wind Velocity	
		Miles/Hour	Kilometers/Hour
0	calm	0–1	0–1.6
1	light air	1–3	1.6–4.8
2	light breeze	4–7	6.4–11.3
3	gentle breeze	8–12	12.9–19.3
4	moderate breeze	13–18	20.9–29
5	fresh breeze	19–24	30.6–38.6
6	strong breeze	25–31	40.2–49.9
7	moderate gale	32–38	51.5–61.1
8	fresh gale	39–46	62.8–74.0
9	strong gale	47–54	76.5–86.9
10	whole gale	55–63	88.4–101.4
11	storm	64–75	103–120.7
12	hurricane	over 75	over 120.7

Bellamy Method. Devised by J.C. Bellamy in the late 1940s, the Bellamy method estimates the horizontal divergence of air, using a triangular network of rawinsonde stations. At any one altitude, the wind measurements at the vertices of the rawinsonde triangle are linearly interpolated along the sides of the triangle to find the average wind

component perpendicular to the side. When these normal wind components are multiplied by the length of the respective side, summed over all sides, and divided by the area of the triangle, the result is the average horizontal divergence within the triangle. Note that this method is sensitive to wind measurement errors and to the spacing between rawinsondes.

Berg Wind. (Literally, mountain wind.) A hot, dry, squally wind blowing off the interior plateau of South Africa, roughly at right angles to the coast; a type of foehn. Berg winds blow mainly in winter, when a strong anticyclone occupies the interior plateau, producing outflow across the coastal regions of South Africa. They are especially frequent and noticeable on the cool west coast, where they set in suddenly during the morning, bring a temperature rise of 15°–20 °C (59–68 °F), giving maxima of 22°–35 °C (72–95 °F), and cause the relative humidity to fall from nearly 100% to 30% or less. Here, on days when the sea breeze sets in about noon, the temperature drops by 10°–16 °C (50–61 °F) even more suddenly than it had risen at the onset of the berg wind. Berg wind episodes may last two to three days, causing uncomfortable weather for people and damage to crops. At Port Nolloth in southwest Africa, berg winds occur on an average of 48 days a year, June and July having nine each and the whole summer half-year (October through March) a total of only six.

Biennial Wind Oscillation. Fluctuation of the zonal wind with a period of about two years. It is most pronounced in the lower stratosphere over the equatorial region.

Bise. (Also spelled bize.) Name given to the cold northerly, northeasterly, or easterly, postfrontal winds in the Swiss Middleland (the region between the Jura and the Alps) and in various regions of eastern France.

The bise is typically driven by an anticyclone building to the northwest or north of the Alps. According to Wanner and Furger (1990), "the cold air flow from the north and northeast is channeled between the Jura and the Alps and leads to the formation of the bise over the Swiss Middleland and the upper Rhône Valley. Thus, the bise is normally a postfrontal phenomenon and is closely connected with the advection of cold and dry continental air. Typically the classic bise endures about one to three days." The bise is most frequent in spring, when it usually brings fine, bright weather. In winter a special case of the bise occurs when the pressure gradient is produced by a Mediterranean cyclone system to the south of the Alps, bringing moist air in from the Balkans. Accompanied by heavy clouds, snow whirlwinds in the mountains, and rain, snow, or hail, this wind is called a *black bise* (bise noire in Switzerland and Saône in east central France; bise né gre in Aveyron in south central France). In spring the bise can last for several days and bring damaging frosts. In the Morvan in east central France the very dry bise in March is termed hale de mars (drying wind of March). In the Drôme Valley southeast of Valence (southeast France) the name bise brume is given to a moist, mild, and sometimes foggy wind from the northwest.

Bohorok. In northern Sumatra, a warm, dry local wind blowing on the plains of Deli, Langkat, and Lerdang. It is caused by the east monsoon blowing across the Barisan Mountains and descending on the leeward side as a foehn. The bohorok occurs in May and is prevalent through September; it is feared because of its effect on the tobacco plantations on the plains of Deli. On the windward side of the mountains, "bohorok days" have more rain than usual.

Bora. A fall wind with a source so cold that, when the air reaches the lowlands or coast, the dynamic warming is insufficient to raise the air temperature to the normal level for the region; hence it appears as a cold wind. The terms *borino* and *boraccia* denote a weak bora and a strong bora, respectively. The term was originally applied (along with karstbora) to the cold northeast wind on the Dalmatian coast of Croatia and Bosnia in winter when cold air from Russia crosses the mountains and descends to the relatively warm coast of the Adriatic. According to Smith (1987), the bora "has often been considered the prototype fall wind," although recent studies have revealed that some boras have downslope windstorm or hydraulic jump structure. The event often lasts a day or less, although extended events occur with enough frequency that "the longevity of the bora is one of its primary characteristics. A duration of four to six days is not unusual." It is very stormy and squally, the squalls sometimes reaching 50 m s^{-1} or more. F. Defant (1951) distinguishes between cyclonic bora (bora scura) with clouds and rain, covering the whole Adriatic and occurring with a depression over southern Adria, and the dry anticyclonic bora, with a powerful anticyclone over central Europe extending over Dalmatia; the latter is very violent over the land but extends only a short distance out to sea. A local bora also occurs on the east coast of the Adriatic with a cold anticyclone over the Balkans. The term bora is now applied to similar winds in other parts of the world. Well-known examples occur at Novorossiisk on the northern shore of the Black Sea, and in Novaya Zemlya (islands in the Russian Arctic). A squally katabatic wind at Alme Dagh in the Gulf of Iskenderon (eastern Mediterranean Sea) is termed rageas (also ragut, ghaziyah). The Bulgarian term is buria. In some mountainous regions of the world bora has been further generalized to represent any large mesoscale or synoptic-scale downslope flow of cold air, including post- arctic-frontal fall winds and cold-air downslope windstorms, which may have a hydraulic jump- like character and structure. In the case of downslope windstorms, some authors have used bora for a cold-advection flow (or one that results in cooling to the immediate lee of the mountain barrier), whereas chinook or foehn, refer to a warm- or neutral-advection wind (or one that results in warming or no temperature change leeward of the barrier). Those who have attempted to classify downslope windstorms, however, have found that many cases do not fall neatly into one category or the other.

Boulbie. In France, a violent north wind in the Ariége valley south of Toulouse, especially in December and January. It is strong enough to uproot chestnut trees; it is cold and dry, but may pick up snow from the ground and form drifts. See also **Blizzard**.

Bow Echo. A bow-shaped line of convective cells that is often associated with swaths of damaging straight-line winds and small tornadoes. Key structural features include an intense rear-inflow jet impinging on the core of the bow, with book-end or line-end vortices on both sides of the rear-inflow jet, behind the ends of the bowed convective segment. Bow echoes have been observed with scales between 20 and 200 km, and often have lifetimes between 3 and 6 h. At early stages in their evolution, both cyclonic and anticyclonic book-end vortices tend to be of similar strength, but later in the evolution, the northern cyclonic vortex often dominates, giving the convective system a comma-shaped appearance.

Buran. A strong northeast wind in Russia and central Asia. It is most frequent in winter when it resembles a blizzard, that is, very cold and lifting snow from the ground; as such it is called white buran or, on the tundra, purga. A similar wind in Alaska is called burga. The buran also occurs, but less frequently, in summer, when it raises dust clouds; it is then called karaburan. See also **Blizzard**.

Burga. (Also spelled boorga). A northeasterly storm in Alaska, bringing sleet or snow; it is similar to the winter buran or purga of Russia and Siberia.

Breeze. In general, any light or moderate wind. A land breeze is a coastal breeze blowing from land to sea, caused by temperature difference when the sea surface is warmer than the adjacent land. It usually blows by night, thus alternating with a sea breeze, which blows from sea to land on relatively calm, sunny, summer days when the sea surface is colder than the adjacent land. A lake breeze blows from the surface of a large lake onto the shores during the afternoon. Like land and sea breezes, it is caused by a difference in surface temperature of land and water. See **Beaufort Wind Scale**.

Brisa. (Also spelled briza.) Spanish word for "breeze," usually applied to northeasterly winds blowing off the sea. It has a number of specific applications: 1) On the east coast of Brazil and in Venezuela, it refers to the northeast trade wind; 2) at Montevideo, Uruguay, it is a strong breeze, possibly a sea breeze; 3) in the Philippines, it refers to the northeast monsoon; 4) in northern Puerto Rico, brisa is the northeast trade wind deflected to the east by the east–west mountain ridge; and 5) in Colombia, South America, it is a light, damp breeze. Brisa is also used to denote either or both components of a land and sea breeze system.

Broeboe. A fairly strong, gusty, easterly monsoon wind in the north of the Spermunde Archipelago off the southwest Celebes. It crosses the mountains as a dry foehn.

Burster. (Or southerly burster; also called buster, southerly buster.) A sudden shift of wind to the southeast in the south and southeast parts of Australia, especially frequent on the coast of New South Wales near Sydney in summer. It occurs in the rear of a trough of low pressure that is followed

by the rapid advance of an anticyclone from west Australia. After some days of hot, dry northerly wind, heavy cumulus clouds approach from the south, the wind drops to calm and then sets in suddenly from the south, sometimes reaching gale force. Temperature at Sydney has fallen from 38 °C (100 °F) to 18 °C (64 °F) in thirty minutes. The average summer frequency of bursters at Sydney is 32. Similar winds are experienced in the east of South Africa, especially near Durban.

Buys Ballot's Law. Professor Buys Ballot at Utrecht in 1857 stated this law: "Standing with back to wind, low pressure is to left and high pressure to right in Northern Hemisphere, with the reverse being true in the Southern Hemisphere." This law was one of the earliest statements of the principles of winds now accepted as common meteorological knowledge.

Calm. The absence of apparent motion of the air. In the Beaufort wind scale, a condition of calm is reported when smoke is observed to rise vertically, or if the surface of the sea is smooth and mirrorlike. The National Weather Service reports a wind as calm when it is determined to have a speed of less than three knots (3.5 mph).

Canterbury Northwester. A strong northwest foehn wind descending the New Zealand Alps onto the Canterbury Plains of South Island, New Zealand. The nor'wester (as it is called locally) is responsible for strong, warm, gusty winds that can damage crops, cause uprooting of trees in forests, damage buildings and other structures, and cause soil loss. Its drying action increases the need for irrigation on the Canterbury Plains. It can occur throughout the year but has highest frequency in spring. It generally occurs immediately prior to the passage of a cold front over the South Island. It is responsible for the highest recorded air temperature in New Zealand (42.4 °C (108 °F) at Rangiora on the Canterbury Plains, 7 February 1973).

Canyon Wind.

1. The mountain wind of a canyon, that is, the nighttime down-canyon flow of air caused by cooling at the canyon walls. Because of the steepness of the slopes, canyon winds can be very strong.
2. (Or gorge wind.) Any wind modified by being forced to flow through a canyon or gorge, especially by a strong pressure gradient as is the case with mountain-gap winds. The easterly Wasatch winds of Utah are examples. The speed of canyon winds may be increased as a jet-effect wind (see **Gap Wind**), and their direction is rigidly controlled by the topography.
3. Same as Wasatch winds. See **Wasatch Wind**.

Cardinal Winds. Winds from the four cardinal points of the compass; that is, north, east, south, and west winds.

Channeling. Winds parallel to the main (longitudinal) axis of a mountain valley, resulting from the diversion of momentum from larger-scale winds above ridgetops into the valley. Most commonly, direct transfer of momentum into the valley by mixing or by an impressed large-scale pressure gradient produces a flow along the valley axis that represents a component of the larger-scale flow, that is, in the same direction as the flow aloft. Occasionally, however, the perpendicular geostrophic wind relationship between the pressure gradient and the large-scale wind can lead to situations where the impressed pressure gradient produces a flow in the valley in the opposite direction to the along-valley component of the large-scale flow above the ridgetops.

Chergui. An east or southeast desert wind in Morocco (North Africa), especially in the north. It is persistent, very dry and dusty, hot in summer, cold in winter. It blows with high pressure in the Mediterranean and isobars run nearly parallel with the coast. It is said to be most frequent in the 40 days following 11 or 12 July, a period known as the Smaïm.

Chinook. The name given to the foehn in western North America, especially on the plains to the lee or eastern side of the Rocky Mountains in the United States and Canada. See **Foehn**. On the eastern slopes of the Rocky Mountains the chinook generally blows from the west or southwest, although the direction may be modified by topography. Often the chinook begins to blow at the surface as an arctic front retreats to the east, producing dramatic temperature rises. Jumps of 10°–20 °C (50°–68 °F) can occur in 15 minutes, and at Havre, Montana, a jump from −12° to +5 °C (10° to 41 °F) in 3 minutes was recorded. Occasionally the arctic front is nearly stationary and oscillates back and forth over an observing station, causing the temperature to fluctuate wildly as the station comes alternately under the influence of warm and cold air. As in the case of any foehn, chinook winds are often strong and gusty. They can be accompanied by mountain waves, and they can occur in the form of damaging downslope windstorms. The air in the chinook originates in midtroposphere above the ridgetops, and its warmth and dryness result from subsidence. When moisture is present, a variety of mountain-wave clouds and lee-wave clouds can form, such as the chinook arch of the Canadian Rocky Mountains west of Calgary, Alberta. The chinook brings relief from the cold of winter, but its most important effect is to melt or sublimate snow: A foot of snow may disappear in a few hours. As with the foehn, researchers have attempted to classify chinooks as downslope winds with warming and boras as those accompanied by cooling. Again, these schemes have produced limited success because of the many ambiguous or erroneously classified cases. In other mountain regions, the foehn has a variety of local names, among which are "zonda," "puelche," "aspre," "sky sweeper," and "northwester." See also **Chinook**.

Cross-Valley Wind. A wind that blows across the longitudinal axis of a valley from one sidewall to another. This term is usually applied to a thermally driven (anabatic or katabatic) wind arising when unequal insolation on the two sidewalls causes a strong cross-valley temperature difference. Air then flows toward the more strongly heated sidewall. See **Mountain–Valley Wind Systems**.

Crosswind. A wind that has a component directed perpendicularly to the course (or heading) of an exposed, moving object; more popularly, a wind that predominantly acts in this manner. In the broadest sense, any wind except a direct headwind or direct tailwind is a crosswind. The drift produced by crosswind is critical to air navigation, being especially dangerous during landing and takeoff.

Custard Winds. Cold easterly winds on the northeast coast of England.

Cyclostrophic Wind. Winds that blow as a result of a pressure gradient and centrifugal force, but in the absence of Coriolis force. They are, of necessity, cyclonic, and are restricted to equatorial zones — the only place where Coriolis force is zero, or nearly zero. The cyclostrophic component of a wind is the difference between the gradient wind and the geostrophic wind. Hurricanes are largely cyclostrophic winds, until they travel north or south sufficiently to be affected by Coriolis force.

Dimmerfoehn. A rare and strong south foehn in the Alps, in which the strong foehn winds reach the ground only in the lower parts of the valleys and the plain or foreland. Under these conditions the sea level pressure difference between the south and north side of the Alps is greater than 12 mb. In the upper portions of the valleys, the surface winds are light and variable, as the strong winds do not penetrate to the ground. This effect has been attributed to the persistence of a cold-air layer in the upper valleys, decoupling the surface winds from the flow aloft and making the flow unable to follow the terrain in this region, or to the position of this region with respect to the long mountain wave that may accompany this foehn. The foehn wall and the precipitation area extend beyond the crest across the almost calm surface region in the upper valleys. This condition "is known as 'dimmer-foehn,' meaning blocked or dammed-up foehn."

Doldrums. (Also called equatorial calms). A nautical term for the equatorial trough, especially with reference to the light and variable nature of the winds.

Downburst. An area of strong, often damaging winds produced by a convective downdraft over an area from less than 1 to 10 kilometers (0.6 to 6 miles) in horizontal dimensions.

Downslope Wind. 1. A wind directed down a slope, often used to describe winds produced by processes larger in scale than the slope. Because this flow produces subsidence, downslope winds experience warming, drying, increasing stability, and clearing if clouds are present. 2. Flow directed down a mountain slope and driven by cooling at the earth's surface: a component of the mountain–valley or mountain–plains wind systems; same as katabatic wind.

The many synonyms for downslope flow are sometimes used interchangeably, and this gives rise to ambiguity and confusion. Downslope can be used generically to denote any wind flow blowing down a slope, or it is used specifically for katabatic flows on any scale, such as the nocturnal slope-wind component of mountain–valley wind systems or mountain–plains wind systems. See **Katabatic Wind**, **Gravity Wind**, **Drainage Wind**, **Fall Wind**, **Bora**, **Foehn**, and **Chinook**.

Downslope Windstorm. A very strong, usually gusty, and occasionally violent wind that blows down the lee slope of a mountain range, often reaching its peak strength near the foot of the mountains and weakening rapidly farther away from the mountains. Gust speeds in such winds may exceed 50 m s^{-1} and occasionally strong vortices capable of doing F1 to F2 damage may occur in association with these winds. See **Fujita Scale** in the **Tornado** article. Such windstorms are most likely to the lee of elongated quasi-two-dimensional mountain ranges and can be distinguished from gap winds, which are confined to within or downstream of notable gaps or breaks in a mountain barrier and are generally weaker and less gusty. Downslope windstorms of great severity require an upstream mountain range having a crest at least roughly 1 km (0.6 mi) in height above terrain to its lee, and with a steep leeside slope. Meteorological conditions favoring downslope windstorms are strong synoptic-scale flow across the mountain barrier at the level of its crest, with the cross-range component of the flow either decreasing with height or not increasing too rapidly with height above the crest. Also favorable is high static stability at the level of the mountain crest in the flow approaching the mountain range, decreasing with height above. A mean-state critical level in the middle troposphere, where the flow component across the mountain drops to zero and reverses sign, is often very favorable for downslope windstorms. Downslope windstorms can be considered a gravity wave phenomenon in the sense that vertically propagating gravity waves launched by the passage of stable air over high-amplitude terrain become very steep or break, creating an internal region above the mountain that is characterized by turbulence and a lapse rate approaching the dry adiabatic. Such a region restricts the vertical propagation of energy, allowing the flow near the surface of the mountain to accelerate downslope. Downslope windstorms can also be considered hydraulic jump phenomena in which flow becomes supercritical above and to the lee of a mountain barrier. Downslope windstorms are often known by local names in areas where they occur throughout the world (e.g., the bora along the northeastern shore of the Adriatic Sea and the Taku wind along the Gastineau Channel in southeast Alaska).

Downvalley Wind. (Same as mountain breeze.) A nocturnal, thermally forced along-valley wind produced as a result of nocturnal cooling of the valley air; a nocturnal component of the fair-weather mountain–valley wind systems encountered during periods of light synoptic or other larger-scale flow. Valley cooling is accomplished by the combined effects of draining cold air off the slopes by early-evening downslope (katabatic) winds, and upward motion with upward cold-air advection from the convergence of katabatic flows in the valley center. Air in the valley thus becomes cooler than air at the same level over the adjacent plain, producing higher pressure in the valley. The pressure gradient drives a downvalley wind that begins one to four hours after sunset, persists for the rest of the night until after sunrise, and often reaches 7–10 m s^{-1} or more above the surface. The downvalley wind tends to fill the valley, that is, its depth is approximately the depth of the valley, and where mountains end and a valley empties onto the plains, the downvalley wind can become a cold-air valley outflow jet flowing out of the mouth of the valley.

Drag Anemometer. An anemometer that measures the wind velocity by sensing the drag force on an object, commonly a cylinder or sphere, placed in the flow. The force is proportional to the square of the wind speed.

Drag Sphere Anemometer. A device that measures wind speed by the drag force the wind produces on a solid sphere. Wind speed is proportional to the square root of the drag force. The sphere is often mounted on the end of a rod or pole, with strain gauges attached to the rod to measure the force indirectly.

Drainage Wind. Cold-air-runoff winds that are produced when air in contact with terrain surfaces is cooled and flows downslope and/or downvalley. This generic term is often used to indicate aggregate downslope (katabatic) and downvalley flows, when it is difficult to distinguish between the two. This happens frequently in basins, at the upper end of valleys, in complicated topography where the downslope and downvalley directions are not perpendicular, and in simple valleys when the weaker and shallower downslope flows are masked or overwhelmed by the stronger downvalley flow. Over even gently sloping topography, drainage winds also refer to gravity winds that drain cold air into frost hollows, river valleys, and other lower-lying terrain. See **Downslope Wind**.

Duration. In connection with wind waves, the duration is the length of time that winds generating surface waves have been present. This, in addition to the fetch (which is the distance over which these winds act) and wind direction, determines the amplitude and direction of the wind-generated waves.

Duststorm (or Duster; Black Blizzard). An unusual, frequently severe weather condition characterized by strong winds and dust-filled air over an extensive area. A duststorm usually arrives suddenly in the form of an advancing dust wall, which may be miles long and several thousand feet high. Ahead of the dust wall, the air is very hot and the wind is light. Visibility is usually only a few yards (meters), and is sometimes reduced to nightlike darkness. Prerequisite to a duststorm is a period of drought over an area of normally arable land, thus providing the very fine particles of dust which distinguish a duststorm from the more common sandstorm of desert regions. The sand particles carried by the strong winds of a sandstorm are mostly confined to the lowest 10 feet (3 meters) and rarely rise more than 50 feet (15 meters) above the ground. In U.S. weather observing practice, if blowing dust reduces visibility to between 5/8 and 5/16 statute mile, a "duststorm" is reported; if the visibility is reduced to below 5/16 statute mile, it is reported as a "severe duststorm." Duststorm winds can also be associated with thunderstorm outflows and gust fronts. While these are often shorter-lived than synoptically forced duststorms, they can be quite intense, with an impressive leading edge of the dusty gust front, sometimes called a *dust wall*.

Easterlies. Any winds with components from the east, usually applied to broad currents or patterns of persistent easterly winds, the "easterly belts," such as the equatorial easterlies, the tropical easterlies, and the polar easterlies. (1) The ***equatorial easterlies*** (also called *deep trades*, *deep easterlies*) refer to the trade winds, in the summer hemisphere, when they are very deep, extending to a least 8–10 km (5–6 mi) altitude, and generally not topped by upper westerlies. If upper westerlies are present, they are too weak and shallow to influence the weather. In the winter hemisphere, these easterlies are restricted to a narrow belt along the equator. (2) The ***tropical easterlies*** (also called *subtropical easterlies*) refer to the trade winds when they are shallow, exhibit a strong vertical shear, and give way at about 1.5 km (0.9 mi) to the upper westerlies (antitrades), which then govern the course of cloudiness and weather. The tropical easterlies occupy the poleward margin of the tropics in summer and can cover most of the tropical belt in winter. (3) The **polar easterlies** are a rather shallow and diffuse body of easterly winds located poleward of the subpolar low-pressure belt, and appreciable in the Northern Hemisphere, in the mean, only north of the Aleutian low and the Icelandic low. (4) ***Krakatoa winds*** (also spelled Krakatau), formerly called *overtrades*, is the name given to a layer of easterly winds over the tropics, at an altitude of about 18–24 km (11–15 mi). This layer tops the midtropospheric westerlies (the antitrades), is at least 6 km (3.7 mi) deep, and is based at about 2 km (1.2 mi) above the tropopause. This easterly current is more prominent and better defined in the summer hemisphere. The name is derived from the observed behavior of the volcanic dust carried around the world after the great eruption of Krakatoa (6° S, 105° E) in 1883.

Ekman Spiral.

1. As used in meteorology, an idealized mathematical description of the wind distribution in the planetary boundary layer, within which the Earth's surface has an appreciable effect on the air motion. The model is simplified by assuming that within this layer the eddy viscosity and density are constant, the motion is horizontal and steady, the isobars are straight and parallel, and the geostrophic wind is constant with height. The x direction is taken along the pressure gradient; the resulting approximate equations for the component wind speeds U and V in the x and y directions, respectively, at any level z are

$$U = -Ge^{-\beta}\sin\beta,\ V = G(1 - e^{-\beta}\cos\beta),$$

where G is the geostrophic wind speed, $\beta = z(f/2K_M)^{\frac{1}{2}}$, f is the Coriolis parameter, and K_M is the eddy viscosity. The lowest level H where $U = 0$, so that the true wind and the geostrophic wind have the same direction, is called the geostrophic wind level (or gradient

wind level). It is given by

$$H = (2K_M/f)^{1/2}\left(\tfrac{3}{4}\pi + \alpha_0\right),$$

where α_0 is the angle between the surface wind and the surface isobars. At this height the magnitude of the true wind will exceed that of the geostrophic wind by a small amount, depending on the value of β. The Ekman spiral is an equiangular spiral having the geostrophic wind as its limit point. Below the geostrophic wind level the wind blows across the isobars toward low pressure, at an angle that is a maximum at the surface and does not exceed 45°. The deviation of the wind vector from the geostrophic wind vector diminishes upward at an exponential rate. The theory of this spiral was developed by Ekman in 1902 for motion in the upper layers of the ocean under the influence of a steady wind. It was applied to the atmosphere by Å kerblom in 1908.

2. As originally applied by Ekman to ocean currents, a graphic representation of the way in which the theoretical wind-driven currents in the surface layers of the sea vary with depth. See also **Ekman Spiral (Oceanography)**.

Equatorial Easterlies: (also called *Deep Trades*, *Deep Easterlies*). As used by some authors, the trade winds in the summer hemisphere when they are very deep, extending to at least 8–10 km (5–6 mi) altitude, and generally not topped by upper westerlies. If upper westerlies are present, they are too weak and shallow to influence the weather. In the winter hemisphere, these easterlies are restricted to a narrow belt along the equator.

Equatorial Westerlies. The westerly winds occasionally found in the equatorial trough and separated from the midlatitude westerlies by the broad belt of easterly trade winds. As the air flow in the lower atmosphere is mostly easterly in and about the equatorial trough, the existence of westerlies on mean charts in some areas has been a subject of much interest and speculation. In some regions, this abnormality can be explained as the result of limited areas of west winds on the equatorward side of frequent westward moving cyclones in the equatorial trough. Elsewhere (notably over the Indian Ocean during the Northern Hemisphere summer), the equatorial westerlies may result from the deflection of Southern Hemisphere air as it flows northward across the geographical equator as part of the monsoon. Equatorial westerlies can also be induced on the western side of a large scale localized heating near the equator, such as in the maritime continent.

Etesians. The prevailing northerly winds in summer in the eastern Mediterranean and especially the Aegean Sea; basically similar to monsoon and equivalent to the maestro of the Adriatic Sea. According to the ancient Greeks, the etesians blow for 40 days, beginning with the heliacal rising of Sirius. They are associated (along with the seistan and shamal) with the deep low pressure area that forms in summer over northwest India. They bring clear skies and dry, relatively cool weather. In Greece the etesian wind is locally named the sleeper. In Turkey it is the meltém. The Romans used the word also for the southwest monsoon of the Arabian Sea.

Euros. The Greek name for the stormy, rainy southeast wind. On the Tower of the Winds at Athens it is represented by an old man, warmly clothed and wrapped in his mantle.

Fall Wind. A wind that accelerates as it moves downslope because of its low temperature and greater density. A fall wind is a larger-scale phenomenon than the individual-slope scale and is produced by accumulated cold air spilling down a slope or over a mountain range. The cold air often either accumulates on a plateau or other elevated terrain, or is part of an extensive cold air mass approaching a mountain range as a cold front. Fall winds may have a hydraulic character similar to water flowing over a dam, and one of the details of this flow is that the acceleration of the cold air begins to occur before the crest of the mountain range and therefore before the down-sloping portion of the topography. Fall winds are especially well developed as strong easterly winds on the coast of Norway, and for some distance inland; here they give a narrow strip of fine weather along the shore. They are also well developed on the northern coast of the Aegean Sea. At the southeastern tip of rocky Hagion Oros Peninsula in Greece, Mt. Athos rises to 2033 m (6670 ft) and descends steeply to the sea; northerly winds are disturbed by this great mass and descend as the cold northeasterly Athos fall wind, often of gale force, extending several kilometers out to sea. On the coast of Peru the name is given to sudden heavy gusts that often come down from the high land after onset of the sea breeze. At Rio de Janeiro, Brazil, descending squalls from the northwest are termed terre altos. In the Antarctic fall winds off the inland ice form violent blizzards. Other examples of fall winds are the mistral, papagayo, and vardar. Some authors have generalized this term to refer to downslope winds forced by large meso- and synoptic-scale processes (i.e., scales larger than that of an individual slope), even if they do not represent flows of colder air. Thus, under this nonstandard definition, the foehn and chinook could be considered fall winds.

Fallout Winds. Those tropospheric winds that carry radioactive fallout materials (primarily materials produced by atmospheric tests of nuclear weapons). These winds are observed by standard winds-aloft observation techniques. Fallout winds are used to construct radioactive fallout plots and ground fallout plots.

Foehn (or Föhn) . A warm dry wind on the lee side of a mountain range, the warmth and dryness of the air being due to adiabatic compression upon descending the slopes. The foehn is characteristic of nearly all mountain areas. The winds are often strong and gusty, sometimes forming downslope windstorms as a result of mountain wave activity. The air in the near-surface flow originates at or above the main crest height of the Alpine barrier, and achieves its warmth and dryness as a result of adiabatic descent. The foehn often replaces a retreating cold air mass from a polar or arctic front, producing dramatic temperature rises that reach 10 °C (50 °F) and occasionally even 20 °C (68 °F) or more, sometimes in a matter of minutes. This is especially true of the south foehn, which blows from northern Italy, where the air is warm, to the north of the Alps (Austria, Germany, Switzerland), where the air is cooler and could be cold arctic air as just described. The north foehn, blowing from a cooler to a warmer region, produces less dramatic temperature changes. The air in the foehn, originating from the mid troposphere, is characteristically clean. Its warm temperatures rapidly melt (or sublimate) snow, sometimes producing flooding, and the extreme dryness can lead to dangerous fire weather conditions. The Alpine foehn has been extensively studied by European scientists, and it is recognized as the type wind for similar downslope winds, resulting from cross-barrier flow, in other parts of the world. In other mountain ranges the foehn has a variety of local names, including chinook in the Rocky Mountains in North America; zonda for a westerly foehn from the Argentine Andes; ljuka in Carthinia (northwestern Croatia); halny wiatr in Poland; austru in Romania; and favogn in Switzerland. A northeasterly foehn descending the Massif Central in France and extending over the Garonne Plain is locally called aspre. A dry wind from the northwest descending the coastal hills in Majorca is named the sky sweeper. In New Zealand a foehn blowing from the New Zealand Alps onto the Canterbury Plains is the Canterbury northwester. A cross- barrier flow that produces strong winds and cooling is called a bora in many parts of the world. Many authors have attempted to classify strong wind events as foehn (or chinook) or bora, for example, for climatologies. These studies have had mixed success: Many wind events are easy to classify, but a number of events are difficult, depending on the data available (most studies attempt to use surface data) and the method used to differentiate between the two types of events.

Fog Wind. (Also called nebelwind.) The humid east wind that crosses the divide of the Andes east of Lake Titicaca and descends on the west in violent squalls; probably the same as puelche. Owing to the adiabatic heating of the descending air, the clouds rapidly disintegrate, leaving a sharply defined cloud wall, similar to the foehn wall.

Free Atmosphere. (sometimes called free air). That portion of the Earth's atmosphere, above the planetary boundary layer in which, the effect of the Earth's surface friction on the air motion is negligible, and in which the air is usually treated (dynamically) as an ideal gas. The base of the free atmosphere is usually taken as the geostrophic wind level.

Friction Layer. The lower layer of air, below the "free atmosphere," where the friction with the Earth's surface affects its flow. Depending upon varying conditions, its thickness is usually from 1,500 to 3,000 feet (457 to 914 meters). The name is commonly used to include the surface and

planetary boundary layers. The effects of friction in creating varying wind conditions are discussed under **Atmosphere (Earth)**.

Gale. In storm-warning terminology, a wind of 28–47 knots (32–54 mph). In the Beaufort wind scale, a wind whose velocity ranges from 28–55 knots (32 to 63 miles per hour) and categorized as follows: moderate gale, 28–33 knots (32–37 mph) Force 7; fresh gale, 34–40 knots (39–46 mph) Force 8; strong gale, 41–47 knots (47–54 mph) Force 9; and whole gale, 48–55 knots (55–63 mph) Force 10.

Gap Wind. A strong, low-level wind through either a relatively level channel between two mountain ranges or a gap in a mountain barrier; originally applied to strong (10–20 m s^{-1}) easterly winds through the Strait of Juan de Fuca between the Olympic Mountains of western Washington State and the mountains of Vancouver Island, British Columbia, Canada.

There they have been defined as "a flow of air in a sea level channel that accelerates under the influence of a pressure gradient parallel to the axis of the channel." As in the case of mountain- gap winds, this term has also been applied to pressure-gradient winds accelerating through a gap in a mountain barrier. The pressure gradient often results from a stable, post-cold-frontal anticyclone approaching the barrier and being partially blocked (*see* blocking) as it ascends the barrier, except for the flow through the gap or channel. The tehuantepecer of Central America is a well- known gap wind by this definition. These flows have sometimes been referred to as jet-effect wind and canyon wind.

Geographic Effect on Winds. The relationship between topography and winds. There are two main mechanisms: 1) topographically modified flow, where existing synoptic- scale winds are modulated or redirected by the presence of mountains or terrain features; and 2) geographically generated flow, where solar heating and nocturnal cooling generate anabatic and katabatic flows and mountain and valley circulations during conditions of weak synoptic winds.

Geostrophic Equilibrium. A state of motion of an inviscid fluid in which the horizontal Coriolis force exactly balances the horizontal pressure force at all points of the field so described:

$$2\boldsymbol{\Omega} \times \mathbf{v}_g = -\alpha \nabla_H p,$$

where $\boldsymbol{\Omega}$ is the vector angular velocity of the earth, $\mathbf{v}_g$ the geostrophic wind velocity, α the specific volume, p the pressure, and ∇_H the horizontal del operator. With respect to cyclone-scale motions in extratropical latitudes, the free atmosphere frequently approaches a state of geostrophic equilibrium.

The assumption of geostrophic equilibrium in certain contexts of the equations of motion, but not in others, is known as quasi-geostrophic equilibrium (or approximation). This compromise arose from the fact that the horizontal divergence of the geostrophic wind grossly fails to estimate the real divergence, which is better represented by the field of vertical motion.

Geostrophic Wind. That horizontal wind velocity for which the Coriolis acceleration exactly balances the horizontal pressure force:

$$f\mathbf{k} \times \mathbf{v}_g = -g \nabla_p z,$$

where $\mathbf{v}_g$ is the geostrophic wind, f the Coriolis parameter, $\mathbf{k}$ the vertical unit vector, g the acceleration of gravity, ∇_p the horizontal del operator with pressure as the vertical coordinate, and z the height of the constant-pressure surface. The geostrophic wind is directed along the contour lines on a constant-pressure surface (i.e., a surface along which the atmospheric pressure is everywhere equal at a given instant), or along the isobars in a geopotential surface (i.e., a surface along which a parcel of air could move without undergoing changes in its potential energy), with low elevations (or low pressure) to the left in the Northern Hemisphere and to the right in the Southern Hemisphere. The speed of the geostrophic wind V_g is given by

$$V_g = -\frac{g}{f}\frac{\partial z}{\partial n},$$

where $\partial z/\partial n$ is the slope of the isobaric surface normal to the contour lines to the left of the direction of motion in the Northern Hemisphere and to the right in the Southern Hemisphere. The geostrophic wind is defined at every point except along the equator. The validity of this approximation in dynamic theory depends upon the particular context.

Geostrophic Wind Level. (Also called *gradient wind level*). The lowest level at which the wind becomes geostrophic in the theory of the Ekman spiral proportional to $(v/\sin\varphi)^{\frac{1}{2}}$, where v is the kinetic eddy viscosity and φ the latitude. In practice, this level is observed to be between 0.75 and 1 mile (1.2 and 1.6 kilometers), and it is assumed that this marks the upper limit of frictional influence on the Earth's surface. The geostrophic wind level may be considered to be the top of the Ekman layer and the base of the free atmosphere. See **Ekman Spiral**.

Ghibli. (Also called chibli, gebli, gibleh, gibli, kibli.) A hot dust-bearing desert wind in Tripolitania (northwestern Libya), similar to the foehn. In Morocco, the analogous gibla is a hot dry wind from between southeast and south. It means "the direction in which one turns," that is, the traditional direction of Mecca.

Glacier Wind (Or Glacier Breeze). A shallow gravity wind, along the icy surface of a glacier, caused by the temperature difference between the air in contact with the glacier and free air at the same altitude. The glacier wind does not reverse itself diurnally as do mountain and valley winds, but it reaches its maximum intensity in the early afternoon. The glacier wind is characterized by strongly turbulent flow. See **Katabatic Wind**.

Gorge Wind. A gap wind or canyon wind through a gorge.

Gradient Wind. Any horizontal wind velocity tangent, at the point in question, to the contour line of a constant-pressure surface (i.e., a surface along which the atmospheric pressure is everywhere equal at a given instant) or to the isobar of a geopotential surface (i.e., a surface along which a parcel of air could move without undergoing changes in its potential energy). At such points where the wind is gradient, the Coriolis acceleration and the centripetal acceleration together exactly balance the horizontal pressure force:

$$\frac{V_{gr}}{R} + fV_{gr} = -g\frac{\partial z}{\partial n},$$

where V_{gr} is the gradient wind speed, R the radius of curvature of the path, f the Coriolis parameter, g the acceleration of gravity, z the elevation of the constant-pressure surface, and n the direction normal to the streamline and contour toward decreasing elevation, that is, to the left of the direction of flow in the Northern Hemisphere and to the right in the Southern Hemisphere. Since $R>0$ for cyclonic flow and $R<0$ for anticyclonic flow, it follows that the cyclonic gradient speed is less than (and the anticyclonic gradient speed is greater than) the geostrophic wind speed for the same latitude and pressure force.

Gravity wind. (Also called *drainage wind*.) A wind resulting from cold air running or flowing down a slope, caused by greater air density near the slope than at the same altitude some distance horizontally from the slope. Generally used when cold air is locally generated by a chilled slope surface during periods of weak synoptic or other larger-scale winds, as with katabatic or drainage winds. Slopes can be gentle as found over rolling topography or into river valleys, or steep as on mountains or mountain ranges. Although usually applied to smaller (individual slope) scale flows, the term is occasionally used to include fall winds, or air advected from a cold source region elsewhere, then spilling over and accelerating down a slope, as with a bora or a cold front passage over orography. See **Downslope Wind**; and **Drainage Wind**.

Gregale. The Maltese and best-known variant of a term for a strong northeast wind in the central and western Mediterranean and adjacent European land areas (stronger than the levante). It occurs either with high pressure over central Europe or the Balkans and low pressure over Libya, when it may continue for up to five days, or with the passage of a depression to south or southeast, when it lasts only a day or two. It is most frequent in winter. The weather varies with the type of pressure distribution and the onshore or offshore direction of the wind. In Malta the gregale raises dangerous seas in the harbor. The principal variant is the grégal of the Côte d'Azur (French Mediterranean coast), humid and rainy because it is a wind off the Mediterranean deflected by the Alpine Massif (gargal of the Roussillon region). This is mainly a summer wind and dangerous for vines as it favors mildew. In Provençe and Languedoc

(southern France) it is the gregau, in Spain and Minorca guergal, and in Corsica grécale; these winds are cold and dry and bring spring frosts.

Gust. A sudden brief increase in the speed of the wind. A gust is more transient in character than a squall and is followed by a lull or slackening in wind speed. Generally, winds are least gusty over large water surfaces and most gusty over rough land and near high buildings. According to U.S. weather observing practice, gusts are reported when the peak wind speed reaches at least 16 knots (18 mph) and the variation in wind speed between the peaks and lulls is at least 9 knots (10 mph). The duration of a gust is usually less than 20 s. With respect to aircraft turbulence, a gust is a sharp change in wind speed relative to the aircraft; or a sudden increase in air speed due to fluctuations in the air flow, resulting in increased structural stresses upon the aircraft. See also **Gust Front**.

An airplane flying horizontally into an upward gust of air experiences a sudden change of direction of relative wind. This induces a temporary excess of lifting power due to (a) an increase in the relative angle of attack and therefore a larger lift coefficient and (b) the greater, momentary, relative wind of the wing which thereby accelerates the airplane upward. The effect on the occupants is not unlike that of a surface vehicle passing over a bump in the roadway, hence the term "air bump." If the gust is downward, a downward acceleration is produced by the sudden decrease of angle of attack. This is sometimes referred to as an "air pocket" because the occupants feel as if the airplane had entered a region in which there was no air to sustain the lift. Actually, of course, there is practically no difference in the density of air in or out of the regions of the so-called air "bumps" and "pockets."

Gusts, vertical or horizontal, may be experienced particularly during line squalls and thunderstorms. Smaller gusts may be experienced due to convection currents, as when crossing the boundary between land and water, or between green fields and a desert, or above city buildings. Obstructional interferences may also cause gusts, such as updrafts or downdrafts, when approaching or leaving mountainous areas. See also **Gust Front**; and **Wind Shear**.

The relative intensities and the altitudes at which gusts have been encountered are listed in Table 2.

TABLE 2. CHARACTERISTICS OF GUSTS

Factor	Convection Currents	Line Squalls and Thunderstorms	Obstructions
Velocity of gust, knots	3 to 20	15 to 75	3 to 20
Altitude limit, feet of meters	15,000	50,000	Depends upon type obstruction and prevailing wind.
	4572	15,240	

High intensity gusts may be experienced over areas of a large conflagration, or explosion of a nuclear bomb.

Gustiness factor is a measure of the intensity of gusts given by the ratio of the total range of wind speed between gusts and the intermediate periods of lighter wind to the mean wind speed, averaged over both gusts and lulls.

Haboob. (Many variant spellings, including habbub, habub, haboub, hubbob, hubbub.) A strong wind and sandstorm or duststorm in northern and central Sudan, especially around Khartoum, where the average number is about 24 a year. The name comes from the Arabic word habb, meaning "wind." Haboobs are most frequent from May through September, especially in June, but they have occurred in every month except November. Their average duration is three hours; they are most severe in April and May when the soil is driest. They may approach from any direction, but most commonly from the north in winter and from the south, southeast, or east in summer. The average maximum wind velocity is over 13 m s^{-1} (30 mph) and a speed of 28 m s^{-1} (62 mph) has been recorded. The sand and dust form a dense whirling wall that may be 1,000 meters (3,000 feet) high; it is often preceded by isolated dust whirls. During these storms, enormous quantities of sand are deposited. Haboobs usually occur after a few days of rising temperature and falling pressure.

Harmattan. (Also spelled harmatan, harmetan, hermitan.) A dry, dust-bearing wind from the northeast or east that blows in West Africa especially from late November until mid-March. It originates in the Sahara as a desert wind and extends southward to about 5° N in January and 18° N in July. It is associated with the high pressure area that lies over the northwest Sahara in winter and the adjoining part of the Atlantic in other seasons. In summer the cooler onshore southwest monsoon undercuts it, but the harmattan continues to blow at a height of about 2 km (3,000–6,000 ft) and sometimes deposits dust on ships at sea. This conflict of winds causes the so-called West African tornadoes.

Headwind. A wind that opposes the intended progress of an exposed, moving object, for example, rendering an airborne object's airspeed greater than its groundspeed; the opposite of a tailwind. This effect is particularly critical in air navigation; it is of interest to note that a wind direction may have no component opposing the intended course of an aircraft, but because of drift effects, may have a component opposing the aircraft's heading. Also called *opposing wind*.

Heliotropic Wind. A subtle, diurnal component of the wind velocity leading to diurnal shift of the wind or turning of the wind with the sun, produced by the east-to-west progression of daytime surface heating.

Helm Wind. A strong cold northeasterly wind blowing down into the Eden valley from the western slope of the Crossfell Range (893 meters or 2,930 feet) in northern England. Beyond the stormy northeasterly flow, there is a belt of calm on either side of which may be a light westerly wind. The helm wind occurs when the general direction of the wind is between north-northeast and east. A line of cloud (the helm) forms along the crest of the ridge, and above the calm belt a narrow, nearly stationary roll of cloud (the helm bar) rotates about a horizontal axis parallel to the helm bar. It may occur in any month but is most frequent in winter and spring.

Hurricane-Force Wind. In the Beaufort wind scale, a wind with a speed equal to or greater than 64 knots (73 mph) or Beaufort Number 12 (Force 12). Hurricane-force winds are not exclusive to hurricanes; they occur quite often in strong nontropical storms such as the northeaster, or even in severe thunderstorms.

Iron Winds. Northeasterly winds of Central America; they are prevalent during February and March and blow steadily for several days at a time.

Isallobaric Wind. The wind velocity whose Coriolis force exactly balances a locally accelerating geostrophic wind. Mathematically, the isallobaric wind V is defined in terms of the local accelerations but approximated by the allobaric gradient as follows:

$$V_{is} = k \times \frac{1}{f}\frac{\partial V_g}{\partial t} = -\frac{\alpha}{f_2}\nabla_H \frac{\partial p}{\partial t}$$

where k is the vertical unit vector, f the Coriolis parameter, V_g the geostrophic wind, α the specific volume, ∇_H the horizontal deloperator, and p the pressure. The isallobaric wind is thus directed normal to the isallobars toward falling pressure, with magnitude proportional to the allobaric gradient. Because the isallobaric wind is associated with transient effects and because of the many assumptions used in deriving its equation, observational evidence of this wind is unsatisfactory.

Jet-effect Wind. A local wind created by acceleration of the airflow through a gap, constriction, or channel in a mountain range or between ranges. The acceleration can result from a large-scale pressure gradient, or by Venturi acceleration through a constricting passage. Pressure gradients from large-scale processes can occur when a large- scale anticyclone lies on one side of the barrier, as in the case of canyon or Wasatch winds, or when a cold front impinges on a mountain barrier with a gap in it and the cold air mass forces its way through the gap, as in the case of the tehuantepecer. Other jet-effect winds include the düsenwind, the kossava, and gap winds. *See* **Mountain-gap Wind**.

Jet Stream. Relatively strong winds concentrated within a narrow stream in the atmosphere. While this term may be applied to any such stream regardless of direction (including vertical), it is coming more and more to mean only a quasi-horizontal jet stream of maximum winds

embedded in the midlatitude westerlies, and concentrated in the high troposphere. The question of the maintenance of the jet stream is a cardinal problem of theoretical meteorology. Two such jet streams are sometimes distinguished. The predominant one, the polar-front jet stream, is associated with the polar front of middle and upper-middle latitudes. Very loosely, it may be said to extend around the hemisphere, but, like the polar front, it is discontinuous and varies greatly from day to day. A subtropical jet stream is found, at some longitudes, between 20° and 30° latitude and is strongest off the Asian coast. Currently, in the analysis of upper-level charts, a jet stream is indicated wherever it is reliably determined that the wind speed equals or exceeds 50 knots (57.5 mph). See also **Jet Streams**.

Kachchan. A hot, dry, west or southwest wind of foehn type in the lee of the Sri Lanka hills during the southwest monsoon in June and July. It is well developed at Batticaloa on the east coast, where it is strong enough to overcome the sea breeze and bring maximum temperatures of nearly 38 °C (100 °F).

Katabatic Wind. Any wind blowing down an incline; the opposite of anabatic wind. If the wind is warm, it is called a *foehn*; if cold, it may be a *fall wind* , such as the *bora* . The term is often taken as synonymous with *gravity wind* , whose direction down the slope of an incline is caused by greater air density near the slope than at the same levels some distance horizontally from the slope. Gravity wind is usually referred to when the density difference is produced by surface cooling along the incline, as in the case of a mountain wind. Fall winds, on the other hand, are considered to be larger-scale phenomena, such as the motion of cold air from an elevated interior toward an adjacent warm sea coast. See also **Katabatic Wind**.

Kahamsin. (Also spelled camsin, chamsin, kamsin, khamasseen, khemsin.) A dry, dusty, and generally hot desert wind in Egypt and over the Red Sea. It is generally southerly or southeasterly, occurring in front of depressions moving eastward across North Africa or the southeastern Mediterranean. The deep khamsins occur in spring with depressions traveling east-northeast across the northern Sahara. They are preceded by a heat wave lasting about three days and are followed by a duststorm. The passage of the depression is marked by a cold front bringing Mediterranean air and a sudden drop in temperature.

Kona. A stormy, rain-bringing wind from the southwest or south-southwest in Hawaii. It blows about five times a year on the southwest slopes that are in the lee of the prevailing northeast trade winds. Kona is the Polynesian word for "leeward." It is associated with a southward or a southeastward swing of the Aleutian low and the passage of a secondary depression (kona cyclone) from northwest to southeast, north of the islands.

Kossava. (Also spelled kosava, koschawa.) A cold, very squally wind, descending from the east or southeast in the region of the Danube "Iron Gate" through the Carpathians, continuing westward over Belgrade, thence spreading northward to the Rumanian and Hungarian borderlands and southward as far as Nish. In winter it brings temperatures down to below −29 °C (−20 °F) and it is cool even in summer, when it is also dusty. It usually occurs with a depression over the Adriatic and high pressure over southern Russia, a frequent situation in winter. It is usually explained as a jet-effect wind through the Iron Gate, giving speeds well above the gradient wind, but J. Küttner[1940] regards it rather as a katabatic wind intermediate between foehn and bora. The kossava has a marked diurnal variation, with its maximum occurring between 5 and 10 AM.

Krakatoa Winds. (Also spelled Krakatau; formerly called overtrades.) A layer of easterly winds over the Tropics at an altitude of about 18–24 kilometers (11–15 miles). This layer tops the midtropospheric westerlies (the antitrades), is at least 6 kilometers (3.7 miles) deep, and is based at about 2 kilometers (1.2 miles) above the tropopause. This easterly current is more prominent and better defined in the summer hemisphere. It derives its name from the observed behavior of the volcanic dust carried around the world after the great eruption of Krakatoa (6° S, 105° E) in 1883.

Lake Breeze. A wind, similar in origin to the sea breeze but generally weaker, blowing from the surface of a large lake onto the shores during the afternoon; it is caused by the difference in surface temperature of land and water as in the land and sea breeze system. In addition to area, the depth of the lake is an important factor; a shallow lake warms up rapidly and is less effective as the source of a lake breeze in summer than is a deep lake. Lake breezes are well developed around the Great Lakes of North America, where they temper the summer heat.

Lee Cyclogenesis. (Also called *orographic cyclogenesis*.) The synoptic-scale development of an atmospheric cyclonic circulation on the downwind side of a mountain range. The "lee" side is relative to the mean background airflow. Weak development can occur due to a redistribution of uniform vorticity as large-scale flow passes over a mountain barrier (*see* lee trough). Stronger cases of lee cyclogenesis occur when the mountain range interacts with a developing baroclinic wave. In this instance the mountain acts to position the cyclone or generate a secondary cyclone in the lee. Often this leaves a weaker parent cyclone that is typically poleward of the development and far from the mountains. Lee cyclogenesis is a multistage process involving a phase of rapid deepening followed by a transition to slower baroclinic deepening. The mountain barrier disrupts the orderly advection of low-level cold air that would occur behind the cyclone over flatter terrain and induces a quasigeostrophic imbalance. As it tends to restore this imbalance (*see* geostrophic adjustment), the atmosphere produces the beginnings of a cyclonic system near the surface. The lack of cool air at low levels and the descending upper-level air make the mountain lee environment statically less stable than the surroundings. This enhances the possibility for vertical coupling of potential vorticity maxima associated with the approaching upper-level trough and the incipient lee disturbance at lower levels. Lee cyclogenesis is common on the leeward side of the major mountain ranges of the world including the Alps, the Himalayas, the Rockies (both east and west), and the Andes. Many minor ranges support lee cyclogenic activity.

Lee Trough. (Same as dynamic trough.) A pressure trough formed on the lee side of a mountain range in situations where the wind is blowing with a substantial component across the mountain ridge; often seen on United States weather maps east of the Rocky Mountains, and sometimes east of the Appalachians, where it is less pronounced. Its formation may be explained thermodynamically by the warming due to adiabatic compression of the sinking air on the lee side of the mountain range, or dynamically by generation of cyclonic circulation (cyclogenesis) by the horizontal convergence associated with vertical stretching of air columns passing over the ridge and descending the lee slope. Alternatively, the latter viewpoint is often expressed as the conservation of potential vorticity, where the vertical stretching of the columns is compensated by an increase in their relative vorticity. See **Lee Cyclogenesis**.

Levante. The Spanish and most widely used term for an east or northeast wind occurring along the coast and inland from southern France to the Straits of Gibraltar. It is moderate or fresh (not as strong as the gregale), mild, very humid, overcast, and rainy; it occurs with a depression over the western Mediterranean Sea. In summer it is rare and weak; in January it is inhibited by the Iberian anticyclone. It is most frequent from February to May and October to December. A levant (French spelling) with fine weather is a levant blanc; in the Roussillon region of southern France (where, as along the Catalonian coast of Spain, it is called llevant) it often brings floods in the mountain streams. The levanter of the Gibraltar Straits is a related phenomenon.

Levanter. An English name for the levante, more specifically applied to winds in the Straits of Gibraltar and on the east coast of Spain. It blows from east or northeast with high pressure over central Europe and a depression over the southwest Mediterranean. It is most frequent and strongest from October to December and February to May, and persists for two or three days.

Libeccio. Italian name for a southwest wind; used especially in northern Corsica for the west or southwest wind that blows throughout the year, and especially in winter when it is often stormy. On windward slopes it brings rain, with thunderstorms in summer and autumn. After crossing the mountains it is warm and dry, but may be very turbulent.

Local Winds.

1. Winds that differ, over a small area, from those appropriate to the general pressure distribution, or which possess some other peculiarity. Often these winds have names unique to the area where they occur. Local winds may be classified into four main groups: The first includes diurnally varying airflows that are driven by local gradients of surface heat flux (e.g., near the shore of a sea or lake) or by diurnal heating or cooling of the ground surface in areas of

sloping or mountainous terrain. These include land and sea breezes, mountain–valley circulations, and drainage and slope winds. The second group consists of winds produced by the interaction of a synoptic-scale flow with orography. These may be further subdivided into barrier jets, gap winds, downslope windstorms, and include such local phenomena as the tehuantepecer, Santa Ana, foehn, mistral, and bora. The third group includes those winds accompanying convective activity, more specifically individual thunderstorms or mesoscale convective systems. These are generally the surface manifestations of precipitation- cooled diverging outflow and in some locations are given special names due to the distinctive character of the weather associated with them (e.g., the haboob). The fourth group includes winds that are strong because of strong pressure gradients or uninterrupted flow over a level surface, or both, including sand- and snow-bearing winds, and some winds off the sea.

2. Local or colloquial names given to frequently occurring or particularly noteworthy winds (sometimes because of the bad weather associated with them), usually from a certain direction. Often these names reflect the direction from which the wind comes (e.g., sou'wester, nor'easter).

Logarithmic Velocity Profile. The variation of the mean wind speed with height in the surface boundary layer, derived with the following assumptions: (1) the mean motion is one-dimensional; (2) the Coriolis force can be neglected; (3) the shearing stress and pressure gradient are independent of height; (4) the pressure force can be neglected with respect to the viscous force; and (5) the mixing length l depends only on the fluid and the distance z from the boundary, $l = kz$.

Near aerodynamically smooth surfaces, the result is

$$\frac{\overline{u}}{u*} = \frac{1}{k}\ln\left(\frac{u*z}{v}\right) + 5.5,$$

that is, the logarithmic velocity profile, where u * is the friction velocity and v the kinematic viscosity. $k \cong 0.4$ and has been called the Kármán constant or von Kármán's constant. The equation fails for a height z sufficiently close to the surface. For aerodynamically rough flow, molecular viscosity becomes negligible. The profile is then

$$\frac{\overline{u}}{u*} = \frac{1}{k}\ln\left(\frac{z}{z_0}\right), z \geq z_0.$$

z_0 is a constant related to the average height ε of the surface irregularities by $z_0 = \varepsilon/30$ and is called the aerodynamic roughness length. Another derivation of the logarithmic profile was obtained by Rossby under the assumption that for fully rough flow the roughness affects the mixing length only in the region where z andz_0 are comparable. Then $l = k(z + z_0)$ and

$$\frac{\overline{u}}{u*} = \frac{1}{k}\ln\left(\frac{z + z_0}{z_0}\right).$$

Lombarde. An easterly wind (from Lombardy) that predominates along the French–Italian frontier. It comes from the High Alps. In winter it is violent and forms snowdrifts in the mountain valleys. In the plains it is gentle and very dry. It is associated with an anticyclone over France and central Europe, or with high pressure to the southeast of Europe and low pressure to the northwest along with falling pressure over western France.

Long Shore Wind. 1. A damp unpleasant wind that blows from the south in Madras (India). 2. A wind from the northeast at night in Sri Lanka.

Mackerel Breeze. (Also called *Mackerel Gale*) — A wind that ruffles the water, favoring the catching of mackerel.

Maloja Wind. A wind, named after the Maloja Pass between the Engadine and Bergall, Switzerland, that blows down the valley of the Upper Engadine by day and either up or down by night. This deviation from the usual nature of mountain and valley winds is attributed to the fact that the stronger daytime valley wind from the south overtops the ridge and continues down the Engadine.

Marin. A warm moist southeast wind from the sea on the French Mediterranean coast and in the Maritime Alps, especially frequent in spring and autumn. In the Rhône delta it blows also from the south. The marin is associated with depressions that cross southern France or northern Spain and the Gulf of Lions. Generally, it is strong and regular, sometimes violent and turbulent in hilly country as the ayalas in the Massif Central; it is very humid, cloudy with hill fog, and often rainy (unless unaccompanied by fronts, when it is the marin blanc). The heavy rains, which may continue for one or two days on the mountain slopes, cause dangerous river floods. On the western slope of the Cévennes it becomes the autan. In the southern Cévennes the marin is called the aygalas. On the coast of Catalonia (northeast Spain) and Roussillon (southern France) it is the marinada and generally occurs with a depression centered over or south of the Gulf of Gascony.

Matinal. The "morning wind," that is, an east wind. In the Morvan Mountains and the center of the Massif Central in France, the matinal often blows for several days, especially in summer, and brings fine weather. On winter mornings a northeast or east wind descends the western slopes of the Alps (where it is known as the matiniére) bringing cold and generally fine weather.

Maximum-Wind and Shear Chart. (Or max-wind and shear chart.) A synoptic chart on which are plotted the altitudes of the maximum wind speed, the maximum wind velocity (wind direction optional), plus the velocity of the wind at mandatory levels both above and below the level of maximum wind. These maps can be analyzed for one or more of the quantities plotted.

Maximum-Wind Level. (Or max-wind level.) The height at which the maximum wind speed occurs, typically within the jet stream, determined in a winds-aloft observation.

Maximum-Wind Topography. (Or max-wind level.) The height at which the maximum wind speed occurs, typically within the jet stream, determined in a winds-aloft observation.

Meridional Wind. The wind or wind, component along the local meridian, as distinguished from the zonal wind (along the local parallel of latitude). In a horizontal coordinate system fixed locally with the x-axis directed eastward and the y-axis northward, the meridional wind is positive if from the south, and negative if from the north (the zonal wind is positive if from the west, and negative if from the east).

Minuano. A cold southwesterly wind blowing in the winter (June through September) in the coastal region of southern Brazil, the country of the Minuano Indians. It is a weak pampero.

Mistral. A north wind that blows down the Rhone Valley south of Valence, France and into the Gulf of Lions. It is strong, squally, cold, and dry; the combined result of the basic circulation, a fall wind, and jet-effect wind. It blows from the north or northwest in the Rhône Delta, where it is strongest, from northwest in Provence and from the northeast in the valley of the Durance below Sisteron. A general mistral usually begins with the development of a depression over the Tyrrhenian Sea or Gulf of Genoa with an anticyclone advancing from the Azores to central France. It often exceeds 27 m s^{-1} (60 mph) and reaches 38 m s^{-1} (85 mph) in the lower Rhône valley and 22 m s^{-1} (50 mph) at Marseilles, decreasing both east and west and out to sea. It remains strong to a height of 2–3 km. In the absence of a strong pressure gradient, a weaker katabatic local mistral develops in the Rhône valley. A general mistral usually lasts for several days, sometimes with short lulls. It is most violent in winter and spring, and may do considerable damage. Market gardens and orchards are protected from it by windbreaks, and rural houses are built with only a few openings on the side exposed to it. The mistral has a variety of local names: mangofango in Provence; sécaire, maistrau, maistre, or magistral in Cévennes; dramundan in Perpignan; cierzo in Spain; cers in the Pyrenees, etc. South of Mont Ventoux a similar wind is named bise. A local west wind of mistral type that descends from Mt. Canigou to the plains of Roussillon is called canigonenc.

Moazagotl Wind. The strong wind blowing across a mountain crest, responsible for the formation of the Moazagotl cloud. See also **Clouds and Cloud Formation**.

Monsoon. A name for seasonal winds (derived from Arabic *mausim*, a season). It was first applied to the winds over the Arabian Sea, which blow for six months from northeast and for six months from southwest, but it has been extended to similar winds in other parts of the world. Even in Europe, the prevailing west-to-northwest winds of summer have been called the "European monsoon." The primary cause is the much

greater annual variation of temperature over large land areas compared with neighboring ocean surfaces, causing an excess of pressure over the continents in winter and a deficit in summer; but other factors, such as the relief features of the land, have a considerable effect. Thus, monsoons are strongest in Asia, the largest land mass, but also occur on the coasts of tropical regions wherever the planetary circulation is not strong enough to inhibit them. Monsoon winds have been described in Spain, Australia, Africa, the United States, and Chile. In India, the term is popularly applied chiefly to the southwest monsoon and, by extension, to the accompanying rains.

Monsoon Depression. A depression that forms within the monsoon trough. The term is most frequently used to describe weak cyclonic disturbances that form over the Bay of Bengal and generally track northwestward over the Indian subcontinent. These occasionally intensify into tropical cyclones if they remain over warm ocean water long enough. The term is also used to describe depressions that form within the monsoon trough near Australia and in the western North Pacific region. The term has gained ascendancy in use to refer to a broad tropical cyclonic vortex characterized by 1) its large size, where the outermost closed isobar may have a diameter on the order of 600 n mi (1,000 km); 2) a loosely organized cluster of deep convective elements, which may form an elongated band of deep convection in the east semicircle; 3) a low- level wind distribution that features a 100 n mi (200 km) diameter light-wind core, which may be surrounded by a band of gales or contain a highly asymmetric wind field; and 4) a lack of a distinct cloud system center. Most monsoon depressions that develop in the western North Pacific eventually acquire persistent central convection and accelerated core winds, marking their transitions into conventional tropical cyclones.

Monsoon Gyre. A convection of the summer monsoon circulation of the western North Pacific characterized by 1) a very large nearly circular low-level cyclonic vortex (not the result of the expanding wind field of a preexisting monsoon depression or tropical cyclone) that has an outermost closed isobar with a diameter on the order of 1200 n mi (2500 km); 2) a cloud band bordering the southern through eastern periphery of the vortex/surface low; and 3) a relatively long (two week) life span.

Initially, a subsequent regime exists in its core and western and northwestern quadrants with light winds and scattered low cumulus clouds; later, the area within the outer closed isobar may fill with deep convective cloud and become a isobar or tropical cyclone. Note: a series of midget tropical cyclones may emerge from the "head" or leading edge of the peripheral tropical cyclone of a monsoon gyre.

Mountain-Gap Wind. A local wind blowing through a gap between mountains, a gap wind. This term was introduced by R. S. Scorer[1952] for the surface winds blowing through the Strait of Gibraltar. When air stratification is stable, as it usually is in summer, the air tends to flow through the gap from high to low pressure, emerging as a "jet" with large standing eddies in the lee of the gap. The excess of pressure on the upwind side is attributed to a pool of cold air held up by the mountains. Similar winds occur at other gaps in mountain ranges, such as the tehuantepecer and the jochwinde, and in long channels, such as the Strait of Juan de Fuca between the Olympic Mountains of Washington and Vancouver Island, British Columbia.

Mountain–Plains Wind Systems. The diurnal cycle of local winds between a mountain or a mountain range and the adjacent or surrounding plains during periods of weak synoptic flow. Winds at lower elevations blow from the plains toward the mountains during daytime and from the mountains toward the plains at night. An upper return branch of the circulation at higher levels is sometimes present, blowing in the direction opposite the surface winds and completing the circulation. The mountain-plains wind system is most apparent on individual days when skies are clear and the general prevailing winds are weak, but it is also seen in climatological averages. The term is usually used to represent the larger massif-scale circulations, of which the embedded along-valley wind systems and along-slope wind systems are key components. On the smaller mountain and mountain-range scale, the components of the diurnal cycle are a nocturnal mountain (katabatic) wind and a daytime wind from the plains toward the mountains (anabatic wind).

Mountain–Valley Wind Systems. A system of diurnal winds along the axis of a valley, blowing uphill and upvalley by day (anabatic wind), and downhill and downvalley by night (katabatic wind); they prevail mostly in calm, clear weather. The upvalley component, or valley wind, usually sets in about one-half hour before sunrise and continues until about one-half hour before sunset. On southerly slopes, it may reach 14 miles (22.5 kilometers) per hour; on northerly slopes, it is barely noticeable. The downvalley component, or mountain wind, is due to nocturnal cooling, and blows at night. It is somewhat weaker than the valley wind, reaching up to 9 miles (14.5 kilometers) per hour.

Observationally, these compensatory currents have been verified in some cases but not found in others. The classic model has the upvalley wind continuing until after sunset, but in many semiarid regions (or during dry periods), when the Bowen ratio is large and the surface heat flux is strong, boundary layer convection interrupts this model by mixing ridgetop winds down to the surface for much of the mid- to late afternoon. Where the valley opens onto a plain, a valley outflow jet, which represents a continuation of the downvalley wind, often extends many kilometers over the plain at night. Variations from this basic scheme arise from valley orientation, especially affecting the transition periods. In a north–south valley, for example, sunset occurs first on the east-facing slopes, and katabatic flows begin earlier there, which can result in cross-valley winds connecting with anabatic flow components on the west-facing sidewalls still in the sun. Similarly, at sunrise the east-facing slope is exposed to sunshine earlier than the rest of the valley, and therefore anabatic flows begin earlier there.

Mountain Wind. A nocturnal, thermally forced wind from the direction of the mountains, generated by cooling along the mountain slopes; a downvalley wind, or the nighttime downslope (katabatic) component of a mountain–plains wind system.

N'aschi. (Also spelled nashi.) The Arabic name for a northeasterly wind that occurs in winter on the Iranian coast of the Persian Gulf, especially near the entrance to the gulf and also on the Makran coast. It is probably of the bora type, though less strong, representing the outflow of cold air from central Asia. The n'aschi is part of the Asiatic monsoon system.

Narbonnais. (Also spelled narboné.) In France, a wind coming from Narbonne; a north wind in the Roussillon region of southern France resembling the tramontana.

If associated with an influx of arctic air, it may be very stormy with heavy falls of rain or snow. It is especially violent in the region of Perpignan where it blows in a succession of squalls for several days. In Provence it is rarer and blows from the west. In lower Languedoc and the southern Cévennes, the narbonnais is an infrequent, mild, moist, moderate southwest wind in winter and early spring, sometimes bringing thunderstorms.

Near Gale. Wind with a speed between 28 and 33 knots or force 7 on the Beaufort wind scale.

North Foehn. A northerly foehn wind blowing down the Italian side of the Alps. The northern slopes are normally cooler than the southern slopes, and the dynamic warming is often insufficient to overcome the difference of temperature. Hence a warm dry northerly wind of foehnlike character occurs less frequently than the south foehn.

Norther. A northerly wind; in general, a cold windstorm from the north. The term has several specific applications: 1) In the southern United States, especially in Texas (Texas norther), in the Gulf of Mexico, in the Gulf of Panama away from the coast, and in Central America (norte), the norther is a strong cold wind from between northeast and northwest. It occurs between November and April, freshening during the afternoon and decreasing at night. It is a cold air outbreak associated with the southward movement of a cold anticyclone. It is usually preceded by a warm and cloudy or rainy spell with southerly winds. The norther comes as a rushing blast and brings a sudden drop of temperature of as much as 25 °F in one hour or 50 °F in three hours in winter. 2) The California norther is a strong, very dry, dusty, northerly wind that blows in late spring, summer, and early fall in the valley of California or on the West Coast when pressure is high over the mountains to the north. It lasts from one to four days. The dryness is due to adiabatic warming during descent. In summer it is very hot. 3) The Portuguese norther is the beginning of the trade wind west of Portugal. 4) Norther is used for a strong north wind on the coast of Chile that blows occasionally in summer. 5) In southeast Australia, a hot dry wind from the desert is called a norther.

NRM Wind Scale. A wind scale adapted by the U.S. Forest Service for use in the forested areas of the northern Rocky Mountains (sometimes abbreviated NRM). It is an adaptation of the Beaufort wind scale. The difference between these two scales lies in the specification of the visual effects of wind; the force numbers and the corresponding wind speeds are the same in both.

Onshore Wind. A wind blowing from water onto land; the wind may be a result of heating differences between land and water or related to synoptic weather patterns.

Orographic Wind Flow. Wind flow caused, affected, or influenced by mountains. Orographic effects include both dynamic, in which mountains disturb or distort an existing approach flow, and thermodynamic, in which heating or cooling of mountain-slope surfaces generates flow. See also **Orographic Vortex**. Dynamic effects include aerodynamic obstacle effects, mountain waves, channeling, orographic blocking, and processes leading to foehn, bora, and gap winds. Thermodynamic effects include anabatic winds, katabatic winds, valley breezes, and mountain breezes. See **Mountain–Valley Wind Systems**; and **Mountain–Plains Wind Systems**.

Osos Wind. In California, a strong northwest wind blowing from the Los Osos valley to the San Luis valley.

Pampero. A cold squally south or southwest wind over the pampas of the Argentine and Uruguay, which sets in with the passage of a cold front; the South American counterpart of a norther. It is often accompanied by squalls, thunderstorms, and a sudden drop of temperature. The pampero seco is rainless; the pampero sucio brings a duststorm.

Papagayo. (Also spelled popogaio.) A violent northeasterly fall wind on the Pacific coast of Nicaragua and Guatemala. It consists of the cold air mass of a norte that has overridden the mountains of Central America and, being a descending wind, brings fine clear weather. Papagayos are most frequent and strongest in January and February, often lasting three or four days. They weaken between 7 and 10 AM and freshen again, sometimes to gale force, in the evening and early night.

Polar Wind. The permanent outflow of ionization from the polar regions of the magnetosphere.

Prevailing Wind Direction. (Or prevailing wind.) The wind direction most frequently observed during a given period. The periods most frequently used are the observational day, month, season, and year. Methods for determination vary from a simple count of periodic observations to the computation of a wind rose. See **Resultant Wind**.

Puelche. An east wind that has crossed the Andes; the Andean foehn of the South American west coast. This term is sometimes used for a land breeze in areas where the Andes descend sharply into the Pacific Ocean. The corresponding sea breeze is the virazon. See **Fog Wind**.

Radial Wind. Component of the wind at a point in a direction along a radius vector from the center of a circulating wind system.

Relative Wind. Velocity of air with reference to a body in it; usually determined by measurements made at such a distance from the body that the disturbing effect of the body upon the air is negligible. The airspeed indicator, for example, located in an airplane, measures the speed of the relative wind. Equations dealing with aerodynamic forces are based upon the velocity of the relative wind.

Resultant Wind. In climatology, the vectorial average of all wind directions and speeds for a given level at a given place for a certain period, such as a month. It is obtained by resolving each wind observation into components from south and west, summing over the given period, obtaining the averages, and reconverting the average components into a single vector. See **Wind Rose**.

Santa Ana. In the United States, a dry, foehnlike desert wind in southern California, generally blowing from the northeast or east, especially in the pass and river valley of Santa Ana, California, and other nearby passes, where it is further modified as a mountain-gap wind. It is driven by strong pressure gradients from an anticyclone over the Great Basin of the western United States. It blows, often hot and sometimes with great force, from the deserts to the east of the Sierra Nevada Mountains and may carry a large amount of dust. The combination of heat, dryness, and strong winds make it an especially hazardous fire weather condition. It most frequently occurs in late fall and winter (October–March); when it comes in spring, however, it can do great damage to fruit trees.

Sea Turn. A wind coming from the sea, often bringing mist. The use of this term is limited mainly to New England.

Seistan. A strong wind of monsoon origin that blows from between the northwest and north-northwest and sets in about the end of May or early June in the historic Seistan district of eastern Iran and Afghanistan. Also called bad-i-sad-o-bistroz.

It continues almost without cessation until about the end of September. From its duration it is known as the wind of 120 days (bad-i-sad-o-bistroz). It sometimes reaches a velocity of more than 31 m s^{-1} (70 mph) and carries much sand and dust. This sand blast is very erosive; buildings are eaten away and undercut near the ground. In some places the sand is deposited as wandering dunes, which overwhelm buildings and choke water supplies. All buildings in the region have blank walls on the windward side. The seistan is associated (along with the European etesians, and the shamal) with the deep summertime low over northwest India.

Shamal. Also called barih; also spelled shemaal, shimal, shumal. The northwest wind in the lower valley of the Tigris and Euphrates and the Persian Gulf. It may set in suddenly at any time, and generally lasts from one to five days, dying down at night and freshening again by day; however, in June and early July it continues almost without cessation (the "great" or "forty-day" shamal). Although the wind rarely exceeds 13 m s^{-1} (30 mph), it is very hot, dry, and dusty. The sky is cloudless but the haze is often so thick as to obscure the land, making navigation dangerous.

Simoom. A strong, dry, dust-laden desert wind that blows in the Sahara, Palestine, Jordan, Syria, and the desert of Arabia. Its temperature may exceed 54 °C (129 °F) and the humidity may fall below 10%. The name means "poison wind" and is given because the sudden onset of a simoom may cause heat stroke. This is attributed to the fact that the hot wind brings more heat to the body than can be disposed of by the evaporation of perspiration.

Sirocco. (Also spelled scirocco.) A warm south or southeast wind in advance of a depression moving eastward across the southern Mediterranean Sea or North Africa. The air comes from the Sahara (as a desert wind) and is dry and dusty, but the term is not used in North Africa, where it is called chom (hot) or arifi (thirsty). In crossing the Mediterranean the sirocco picks up much moisture because of its high temperature, and reaches Malta, Sicily, and southern Italy as a very enervating, hot, humid wind. As it travels northward, it causes fog and rain. In some parts of the Mediterranean region the word may be used for any warm southerly wind, often of foehn type. In the extreme southwest of Greece a warm foehn crossing the coastal mountains is named sirocco di levante. There are a number of local variants of the spelling such as xaroco (Portuguese), jaloque or xaloque (Spanish), xaloc or xaloch (Catalonian). In the Rhône delta the warm rainy southeast sirocco is called eissero. On Zakynthos Island it is called lampaditsa.

South Foehn. A foehn wind blowing from south (northern Italy) to north (Switzerland, southern Germany, and western Austria) over the Alps. Because these winds blow from a warmer region to a cooler region, they are often accompanied by dramatic temperature and wind speed increases. The south foehn often results from flow in the warm sector of a cyclone system and thus it often occurs ahead of a cold front.

Squall.

1. A strong wind characterized by a sudden onset, a duration of the order of minutes, and then a rather sudden decrease in speed. In U.S. observational practice, a squall is reported only if winds speed of 16 knots (18.4 mph) or higher is sustained for at least two minutes (thereby distinguishing it from a gust). See also **Fronts and Storms**.
2. In nautical use, a severe local storm considered as a whole, that is, winds and cloud mass and (if any) precipitation, thunder and lightning.

Streamlines. Lines drawn everywhere tangent to wind vectors. They show the instantaneous flow-pattern of the air at a given time only and do not indicate trajectories of air parcels. Streamlines are used for two-dimensional flows (horizontal plane), although actually they are a three-dimensional function. The vertical velocity is usually considered insignificant in comparison with the horizontal flow. Streamline charts

are useful and quickly-prepared forecast tools for obtaining wind forecasts at a given flight altitude. Trajectory charts, however, are more useful for projecting atmospheric phenomena.

Subtropical Calms. The light and variable winds that occur in the centers of the subtropical high pressure belts over the oceans.

Surface Wind. The wind measured at a surface observing station. This wind is customarily measured at a standard distance above the ground to minimize the distorting effects of local obstacles and terrain.

Tailwind. A wind that assists the intended progress of an exposed, moving object, for example, rendering an airborne object's groundspeed greater than its airspeed; the opposite of a headwind. The tailwind component is directed along the heading, not the course. Also called *following wind.* See **Headwind**.

Taku Wind. A strong, gusty, east-northeast wind, occurring in the vicinity of Juneau, Alaska, between October and March. It sometimes attains hurricane force at the mouth of the Taku River, after which it is named.

Tehuano. A Spanish term frequently used to denote a burst of strong offshore (southward) wind, lasting a day or more, that blows from the Gulf of Mexico across the Gulf of Tehuantepec. Tehuano events are associated with winter surges of cold air that spread southward from the United States across the Gulf of Mexico behind strong weather fronts. Tehuanos produce much local cooling of the gulf waters and frequently cause anticyclonic warm-core ocean eddies to form and propagate west-southwestward near 12°–14° N. See **Papagayo**.

Tehuantepecer. A violent squally wind from north or north-northeast in the Gulf of Tehuantepec (south of southern Mexico) in winter. It originates in the Gulf of Mexico as a norther that crosses the isthmus and blows through the gap between the Mexican and Guatemalan mountains. It may be felt up to 160 km (100 miles) out to sea. See **Jet-effect Wind**; **Mountain-gap Wind**; and **Papagayo**.

Thermal Wind. The mean wind-shear vector in geostrophic balance with the gradient of mean temperature of a layer bounded by two isobaric surfaces. Its analogy to the geostrophic wind is best demonstrated by expressing the thermal wind $\mathbf{v}_T$ in terms of the thickness h of the layer:

$$f\mathbf{k} \times \mathbf{v}_T = -g\nabla_p h,$$

where f is the Coriolis parameter, $\mathbf{k}$ the vertical unit vector, g the acceleration of gravity, and$_p$ the del operator in the isobaric surface. The thermal wind is directed along the isotherms with cold air to the left in the Northern Hemisphere and to the right in the Southern Hemisphere. Its magnitude V_T is given by the formula

$$V_T = \left| \frac{g}{f} \frac{\partial h}{\partial n} \right|,$$

where n is a coordinate normal to the thickness lines.

Tidal Wind. A very light breeze that occurs in calm weather in inlets where the tide sets strongly; it blows onshore with rising tide and offshore with ebbing tide.

Touriello. A south wind of foehn type descending from the Pyrenees in the Ariége valley, France. It is especially violent in February and March when it melts the snow, flooding the rivers, and sometimes causing avalanches. It causes a premature spring that forces the buds on fruit trees, which are subsequently killed by frost. In August and September it comes as a strong drying wind, generally lasting three to four days.

Trade Winds. Commonly called Trades, the wind system occupying most of the tropics, which blows from the subtropical highs toward the equatorial trough; a major component of the general circulation of the atmosphere. The winds are northeasterly in the Northern Hemisphere and southeasterly in the Southern Hemisphere; hence, they are known as the northeast trades and southeast trades, respectively. The trade winds are best developed on the eastern and equatorial sides of the great subtropical highs, especially over the Atlantic. In the Northern Hemisphere they begin as north-northeast winds at about latitude 30° N in January and latitude 35° N in July, gradually veering to northeast and east-northeast as they approach the equator. Their southern limit is a few degrees north of the equator. The southeast trades occupy a comparable region in the Southern Hemisphere and similarly change from south-southeast on their poleward side to southeast near the equator. In the Pacific, the trade winds are properly developed only in the eastern half of that ocean, and in the Indian Ocean, only south of about 10°S. They are primarily surface winds, their usual depth being from 3,000 to 5,000 ft (914 to 1,524 m), although they sometimes extend to much greater altitudes. They are characterized by great constancy of direction and, to a lesser degree, speed; the trades are the most consistent wind system on earth. See **Antitrades**, **Tropical Easterlies**, and **Equatorial Easterlies**.

2. A name given to the prevailing westerlies in California and to the northwest winds that blow in Oregon in summer.

Tramontana. A cold wind from the northeast or north, particularly on the west coast of Italy and northern Corsica, but also in the Balearic Islands and the Ebro Valley in Catalonia.

Like the mistral, it is associated with the advance of an anticyclone from the west following a depression over the Mediterranean. Weather is fine with occasional instability showers. In Languedoc and Roussillon (southern France) a similar wind (tramontane) blows from the northwest, but the name is also applied to an invasion of polar air from the northwest, which is squally or tempestuous, dry, and cold except south of the Cévennes where it becomes foehn-like. This type occurs during the filling of a depression in the Gulf of Genoa and persists for eight to twelve days, mainly in winter and early spring; it rises to a peak at midday and weakens at night. On the Côte d'Azur and in eastern Provence, the tramontane is sometimes called the montagnére or montagneuse.

Traverse. A westerly wind in central France. It is moderate to strong, generally squally, humid, and thundery in summer, especially on slopes facing west; it is cold in winter and spring and brings snow or hail showers. In Auvergne it brings continuous rain (the Grand Vent or plouazaou). In the Alps it is cold and squally. Houses in regions subject to the traverse are protected by roughcast or double walls, and in the Mont Cantal part of Auvergne, where it is especially violent, zinc sheets are used on the walls; roofs are built of large stone slabs.

Tropical Easterlies. (Also called *Subtropical Easterlies*). A term applied to the trade winds when they are shallow and exhibit a strong vertical shear. With this structure, the easterlies give way at about 1.5 km (0.9 mi) to the upper westerlies (antitrades), which are sufficiently strong and deep to determine cloudiness and weather. The tropical easterlies occupy the poleward margin of the Tropics in summer and can cover most of the tropical belt in winter.

True Wind Direction. The direction, with respect to true north, from which the wind is blowing; distinguished from magnetic wind direction. In all standard upper-air and surface weather observations, it is the true wind direction that is reported, usually in terms of tens of degrees in the 360° compass. See also **North**; and **True North**.

Upslope Wind.

1. A wind directed up a slope, often used to describe winds produced by processes larger in scale than the slope. Because this flow produces rising atmospheric motion, upslope winds experience cooling, increasing relative humidity, decreasing stability, and, if sufficient moisture is present, the formation of fog, clouds, and precipitation.
2. Flow directed up a mountain slope and driven by heating at the earth's surface under light larger-scale flow conditions; a component of the mountain–valley or mountain–plains wind systems; same as anabatic wind.

Upvalley Wind. A daytime, thermally forced, along-valley component of along-valley wind systems from the direction of the plains or valley toward the mountains, produced by diurnal heating of the valley air; a daytime along-valley component of the mountain-valley wind systems encountered during periods of light synoptic or other larger-scale flow.

The mechanism of the upvalley wind is as follows. Air in the valley heats faster than an equivalent vertical column of air over the adjacent plains as a result of 1) the difference in the ratio of the volume of air heated in each location to the horizontal area intercepting radiation and 2) subsidence over the middle of the valley compensating for the flow up the slopes. The more effective heating in the valley produces a pressure drop in the valley relative to the plains, and this in turn produces an upvalley wind, called the valley breeze, beginning in late morning one to four hours after

sunrise. It often reaches 3–5 m s^{-1} at the surface and >5 m s^{-1} above the surface. Mature upvalley flows tend to fill the valley, that is, the depth of the upvalley flow is approximately equal to the depth of the valley.

Valais Wind. The notable valley wind that blows along the Rhône valley from the upper end of Lake Geneva (Valais Canton). It is sufficiently strong and regular to distort the growth of trees.

Valley Wind. (Or valley breeze.) A wind that ascends a mountain valley (upvalley wind) during the day; the daytime component of a mountain–valley wind system.

Vardar. (Also called vardarac.) A cold fall wind blowing from the northwest down the Vardar valley in Greece to the Gulf of Salonica. It occurs where atmospheric pressure over eastern Europe is higher than over the Aegean Sea, as is often the case in winter. It persists for two or three days with a mean velocity of 5–7 m s^{-1} (10–15 mph), rising to 16 m s^{-1} (35 mph) in squalls. It is strongest where the Vardar River leaves the mountains, but it extends for some distance out to sea. A similar wind, the Struma fall wind, blows in the Struma valley.

Veering Wind. Any clockwise change in wind direction is known as veering of the wind, as opposed to backing of the wind, a counter-clockwise change.

Venturi Effect. An increase in wind speed and decrease of pressure as air flows through a constriction or mountain gap. The relationship between wind speed and pressure is given by Bernoulli's equation, which states that the sum of kinetic energy plus pressure is constant along a streamline.

Virazon. The very strong southwesterly sea breeze experienced where the coastal chains of the Andes Mountains descend steeply to the sea. It sets in at about 10 AM and reaches its greatest strength at about 3 PM In Valparaiso, Chile, on summer afternoons it is so strong that it lifts pebbles in the streets. During the night it is followed by a light land breeze, the terral ("wind of the land").

2. A westerly sea breeze of Spain and Portugal.

Wasatch Winds. In the United States, strong, easterly winds, often locally referred to as canyon winds, blowing out of the mouths of the canyons of the Wasatch Mountains onto the plains of Utah. They are produced by a strong large-scale west to east pressure gradient and are best developed when there is a large high over Wyoming or a vigorous low to the west or southwest in Utah or Arizona. In extreme cases they can exceed hurricane force. The strong winds are mainly limited to the canyons, especially in winter, but in some circumstances extend beyond them onto the plain.

Washow Zephyr. In the United States, a strong downslope wind on the eastern (Nevada) side of the Sierra Nevada in northern California. This term has been applied to two different types of wind: 1) a foehn or chinook wind during the cold season; and 2) an afternoon wind down the east-facing canyons and valleys during the warm season. The latter may result from afternoon convective mixing or may be related to California sea-breeze effects. See **Mountain-Valley Wind Systems**.

Westerlies (also known as Circumpolar westerlies, Circumpolar Whirl, Countertrades, Middle-latitude westerlies, Polar Westerlies, Subpolar Westerlies, Subtropical Westerlies, Temperate Westerlies, Zonal Westerlies, Westerly Belt, and Zonal Winds), in general any winds with components from the west. Specifically, the dominant west-to-east motion of the atmosphere, centered over the middle latitudes of both hemispheres. At the earth's surface, the westerly belt (or west-wind belt, etc.) extends, on the average, from about 35° to 65° latitude. At upper levels, the westerlies extend farther equatorward and poleward. The equatorward boundary is fairly well-defined by the subtropical high-pressure belt; the poleward boundary is quite diffuse and variable. Especially in the Northern Hemisphere, even the annual average westerlies are markedly enhanced in some regions, namely, the jet streams. See **Equatorial Westerlies**.

Westerly Wind Burst. A short-duration low-level westerly wind event along and near the equator in the western Pacific Ocean (and sometimes in the Indian Ocean). This surge may last from one day to several days and is closely linked to deep equatorial convection to its east. The westerly wind burst is most common during El Niñ o years from September to January and in normal years from October to December. It is absent in the Pacific in La Niñ a years. It is also thought to be associated with the Madden–Julian oscillation. The westerly winds are usually greater than 5 m s^{-1} (10 knots), and reach 15–m s^{-1} (30 knots) in well-developed systems. These intense westerly wind bursts are associated with a large cluster of deep convective clouds along the equator and are necessary precursors to the formation of tropical cyclone twins symmetric about the equator.

Wind Profiler. (Also called *wind profiler radar*, *wind profiling radar*.) A radar that is used to measure vertical profiles of the wind. In general the term is applied to Doppler radars operating in the VHF–UHF band (30 MHz–3 GHz) that determine the wind by measuring the line-of-sight Doppler shift of scattered signals (Bragg scattering) from refractive index fluctuations caused by turbulence. The turbulent scattering structures are assumed to be moving with the same average velocity as the wind. The three-dimensional wind vector is determined by using the beam swinging technique of pointing the radar beam in at least three different directions. Another type of wind profiler radar that operates in the VHF–UHF band uses a technique called spaced antenna drift (SAD). SAD radars use a single vertical-beam transmitting antenna and three or more horizontally spaced, vertical-beam receiving antennas. The horizontal wind is determined from the cross correlation of the received echoes and the vertical wind is determined from the Doppler shift of the echoes. In addition to measuring the wind vector, wind profiler radars can also determine several other atmospheric quantities from the power, mean Doppler shift, and Doppler spectral width of the returned signal. These quantities include the strength of turbulence (parameterized by the refractive index structure constant C_n^2), the eddy dissipation rate, atmospheric stability, momentum flux, virtual temperature and heat flux (using the RASS technique), and precipitation rates and drop- size distributions (from scatter from hydrometeors). Doppler lidars and acoustic sounders (sodars) can also be used as wind profilers. The scatterers for lidars are aerosols (for wavelengths around 10 μm) and molecules (for wavelengths less than 1 μm). Acoustic refractive index fluctuations caused by turbulence provide the scattering mechanism for sodars.

Wind Rose. Any one of a class of diagrams designed to show the distribution of wind direction experienced at a given location over a considerable period; it thus shows the prevailing wind direction. The most common form consists of a circle from which 8 or 16 lines emanate, one for each compass point. The length of each line is proportional to the frequency of wind from that direction; and the frequency of calm conditions is entered in the center. Many variations exist. Some indicate the range of wind speeds from each direction; some relate wind directions to other weather occurrences.

Wind Shear. The local variation of the wind vector or any of its components in a given direction. The wind shear at a point is said to be cyclonic or anticyclonic according to the sense of rotation from the wind vector to the shear vector at that point. See also **Wind Shear**.

Yamase. A cool, onshore, easterly wind in the Senriku district of Japan in summer. It originates in the Okhotsk anticyclone and blows over the cold sea, bringing periods of three to seven days of clouds, rain, and fog.

Zonal Wind.

1. The wind, or wind component, along the local parallel of latitude, as distinguished from the meridional wind. In a horizontal coordinate system fixed locally with the x axis directed eastward and the y axis directed northward, the zonal wind is positive if it blows from the west and negative if from the east.
2. Same as westerlies.

Zonda. (Or sondo, viento zonda.) A hot wind in Argentina. The name seems to apply to two winds of quite different origin. 1) The most common use is for a dry foehn wind descending the eastern slopes of the Andes in the central Argentine in winter, probably polar maritime air warmed by descent from the crest, which is some 5500 m (18 000 ft) above sea level. It may exceed a velocity of 11 m s^{-1} (25 mph). Like the foehn, it sometimes begins with a high foehn (zonda de altura) that overrides a layer of cold air in the lee of the mountains, eventually sweeping it away and descending to ground level as zonda de superficie (or just "zonda"), but this initial cold air mass is not always present. The zondas carry a lot of dust in the dry season. 2) It also describes a hot, humid north wind in the pampas, in advance of a depression moving eastward, and preceding the pampero.

WIND SHEAR. A change in wind direction and/or speed over a relatively short distance. For example, a west wind of 30 knots that changes to a northwest wind of 10 knots in 50 meters contains a shear of 45° and 20 knots in that short distance — 0.9° and 0.4 knot per meter. Most winds blow parallel to the Earth's surface and shear is mostly in the horizontal direction. However, in cumulus clouds, showers, and thunderstorms, gust fronts and some cold fronts, shear may also involve the vertical direction, that is, up and downdrafts. Mathematically, shear in its simplest form is

$$\Delta V / \Delta D$$

where ΔV = change in wind vector
ΔD = distance over which the change occurs

Small-scale wind shear is present everywhere in the atmosphere. In some limited meteorological conditions, shear can become quite large. These conditions generally are restricted to various types of fronts, inversions, thunderstorms, showers, and gusty winds. See Fig. 1.

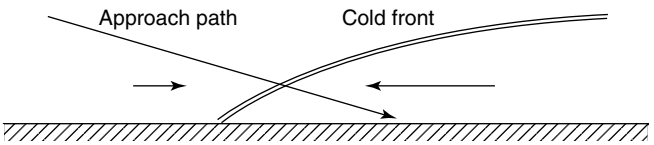

Fig. 1. Schematic illustration (not to scale) of shear of the longitudinal wind component on an approach to an airport from a slight tailwind to a strong headwind.

Wind shear has its greatest impact on aircraft, especially on approach and climb-out to and from airports when the airspeed is nearer critical values than at cruising speeds. Wind shear below 500 meters (1500 feet) is regarded as low-level wind shear. Insofar as aircraft behavior is concerned, shear behaves as if it were in three components:

1. Shear of the longitudinal wind component, that is, the tailwind or headwind
2. Shear of the lateral wind component, that is, the cross wind
3. Shear of the vertical wind component, that is, the downdraft and updraft

Shear of the longitudinal wind component causes acceleration or deceleration of the airflow past the plane and affects the aerodynamically generated lift. If the operating airspeed is well above the stall value, the effect of sheer is seldom, if ever, of sufficient magnitude to create an emergency. However, on an approach or climb-out when the airspeed margin is often small, intense deceleration of the airspeed in shear can induce a borderline aerodynamical performance by the plane.

Shear of the lateral wind component induces an unwanted drift from the planned flight track. Shear of the vertical wind causes the plane to gain or lose altitude in an unplanned manner, which on approach may cause a plane to come too near the earth too soon.

Low-level wind shear is present primarily in and near thunderstorms and showers, in gust fronts, in cold and warm fronts, in sea breeze fronts, in whirlwinds, and gusty winds. Shear of a lesser magnitude is always present near the ground because of the frictional retardation of the wind across the earth.

See also **Fronts and Storms**; **Gust Front**; and other terms listed in entry on **Meteorology**.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

WIND SHOCK. A tapered fabric sleeve, shaped like a truncated cone and pivoted at its larger end on a vertical standard, for the purpose of indicating wind direction. Since the air enters the fixed end, the small end of the cone points away from the wind.

WIND TUNNEL. A device that provides an airstream of known and steady conditions, in which models requiring aerodynamic study are tested. The essential elements of a wind tunnel are: (1) a drive system consisting of either a compressor for continuous operation, or a tank of compressed air for intermittent operation; (2) a test section in which models are held and their orientation is changed; (3) instrumentation capable of reading force, pressure, and other effects produced by the model; and (4) an air efflux system consisting of free exit to the atmosphere or to a vacuum tank, or a tunnel returning the air to the compressor. There are many wind tunnels throughout the world, ranging in test section size from 1 × 1 inch to 30 feet × 60 feet (9.1 × 18.2 meters) with speeds from 50 to 7,000 miles (81 — 11,265 km) per hour and higher. See Fig. 1. See also **Aerodynamics and Aerostatics**.

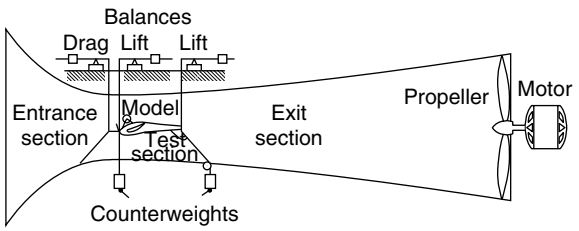

Fig. 1. Simple wind tunnel of the open-circuit and closed-throat type. In some cases, the use of computer simulation has reduced the need for wind tunnel facilities.

With very marked improvements in mathematical modeling and computer simulation, some of the research that formerly required wind tunnels now can be handled by a computer workstation furnished with appropriate

software. An example of the new technology is given in article on "Predicting Propeller Blade Loads without Testing," by Donham, Dupcak, and Conner in *Aerospace Engineering*, 4–9 (April 1987).

Computer simulation, however, does not suffice in all engineering test situations. In October 1990, for example, the largest wind tunnel facility in the world was dedicated by the Center Scientifique et Technique du Batiment (CSTM) in Nantes, France. Known as the Jules Verne wind tunnel, the facility provides 54,000 square feet (5000 m^2) for testing large and small machines and apparatus that are subject to high winds when in use. See also **Weather Technology**.

WINGED FRUIT. See **Fruit**.

WINGNUT TREES. See **Hickory and Wingnut Trees**.

WINRAR. See **Data Compression**.

WINTER EGG. A form of egg produced by some invertebrates, usually in the fall. It has a thick protective shell and in species with a complex life cycle, such as the aphids, it is produced by the sexual generation. Such eggs usually pass through the winter before hatching, but similar eggs may be produced at the beginning of other unfavorable seasons, as periods of drought.

WINZIP. See **Data Compression**.

WIRE DRAWING. The term "wire drawing" has two separate and distinct meanings. First, it is descriptive of the action whereby a rod is reduced to a wire by being pulled forcibly through a round die which reduces its diameter and increases its length (see Fig. 1). Secondly, wire drawing refers to a similar action occurring in fluid flow through a small aperture. The usage in the second case is derived from the first. Wire drawing as applied to a fluid is usually employed in discussions of the flow of steam or gas through the valves of engines. When the valves are partially open, the small area through which a fluid flows causes a reduction of pressure which is known as wire drawing. The description below refers entirely to the production of wires.

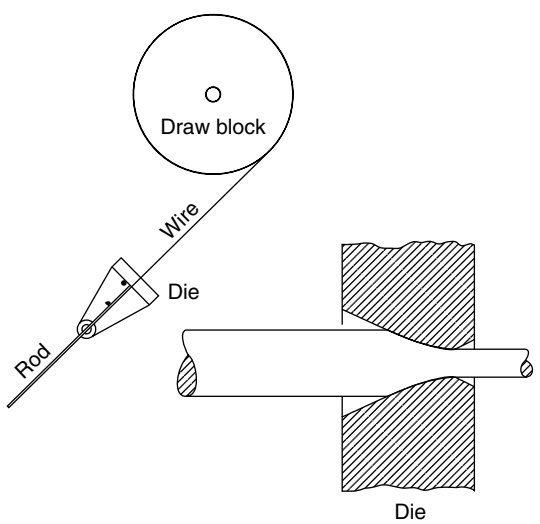

Fig. 1. Wire drawing machine.

To make a wire, the metal is first prepared as a rod by rolling. It is then treated to give it a surface coating which will act as a lubricant during its passage through the die. The method of applying the lubricant gives rise to the wet and dry process of wire drawing. In the dry process the wire is dipped in an emulsion of hydrated lime and dried in baking ovens. Then just before it is passed into the die it passes through a greasing operation. The combination of lime film and grease provides the lubricant between the rod and the die during the drawing process. In the wet process the rod is first dipped in a solution of copper sulfate, which results in a thin coating of copper in the wire. It is then dipped in a vat containing a fermented mixture made from meal and yeast. Upon being withdrawn from this vat, it is fed wet to the die. The liquor, together with the thin copper deposited in the salt bath, lubricates the rod in the wet drawing process.

Drawing consists of pointing the rod and threading it through the die. It is then gripped by pinchers and drawn a short distance by hand power applied through a draw bar. Then the end is clamped in a vise on a revolving drum called the drawblock. This drum is revolved slowly by power applied through a geared shaft, and in so revolving continues to pull the wire through the die until the rod has been completely reduced. When the stock is passed through the die it is elongated and reduced in cross section. The elongation is known as draft, and may amount to from 10 to 40 times the length of the original rod. Sometimes more than one draft is necessary to finish the wire. In such cases it is removed from the block and started through another smaller die.

The dies are the most essential part of wire drawing. They are made of chilled cast iron, steel, cemented carbides, or diamond. The hard cemented carbide type dies are widely used. Diamond dies are used only for fine wire. A typical cross section of a die is shown in the figure. The hole through the die is tapered, and the part where the reduction in wire size occurs is reamed to a very smooth finish. Two tapers are employed, one in which most of the reduction takes place, the other one of smaller taper, in order to ease the wire down to the exact size at exit from the die. The initial part of the tapered hole is not machined, as it serves only as a region for application of the lubricant to the rod. A plan of a draw bench which is the production unit in wire drawing, is also given.

WIRELESS COMMUNICATIONS APPLICATIONS. Statistics show that the level of demand for wireless communications in the past decade has exceeded expectations even when the cost of owning a mobile handset was at its highest. Some of the rational reasons are deregulation of telecommunications monopolies worldwide and adoption of internationally recognized standards by abandoning proprietary standards. Special tariff packages for mobile calls that cause prices to fall due to increased competition and aggressive marketing are being practiced.

It is evident that the wireless communications market has been evolving at an exponential rate since the 1990s and the numbers justify its growth today. One explanation for such growth patterns can be recognized by the replacement of analog by digital standards. Another well-accepted reason is a long-term objective to substitute wired communication with wireless communications technologies. Third world countries that lack a reliable wired-based communications infrastructure are adopting wireless communications technologies as a cheaper alternative. Consequently, wireless communications has proved to be one of the most profitable parts of the telecommunications sector worldwide.

At present, the majority of mobile communications users also own a fixed-link telephone. But, growth in demand for data and Internet-based services has been driving the wired-communication market over the past few years. However, if consumers want to incorporate data, voice, video, and Internet-based services in wireless communications, an infrastructure based on wireless asynchronous transfer mode (WATM) technologies can be used to integrate the best of the two worlds.

OSI Model for the Internet

The open system interconnect (OSI) model divides communication into layers. Each layer fulfills certain tasks and makes different combinations for different applications. The different layers for the Internet models are the network interface layer, Internet layer (equivalent to the network layer on the OSI model and primarily includes IP), transport layer, and the application layer.

Internet Protocols (IP). IP transports packets to the desired destination host on the network. IP is a connectionless protocol and is not aware of any sessions. Every packet is routed independently, and different parts of the same transmission might take a different route. Along the way the packet might be lost, corrupted, duplicated, or delivered out of sequence. If the underlying network is not capable of transmitting packets as large as

those that higher layers try to get IP to send, IP will fragment the packets in order to fit the network.

Transmission Control Protocol (TCP). As a transport layer protocol, TCP ensures that data for which IP finds a destination host will be propagated to the right application. File transfer protocol (FTP) and hypertext transfer protocol (HTTP) applications might be running on the same host, and the TCP port number indicates which is the target application. TCP also ensures that packets of data are delivered reliably and in order. Packets that have traveled different routes in order to get to the same destination need to be assembled in the right order. Finally, TCP provides flow control functionality, which makes sure that the sender and receiver agree on a suitable speed of data delivery. Covering the lost of packets and the maintenance of flow control are the two features that affect wireless performance the most. See also **Transmission Control Protocol (TCP) / Internet Protocol (IP) Suite**.

Hypertext Transfer Protocol (HTTP). HTTP is a protocol that handles the transfer of Web pages and relies on TCP on the transport layer for the reliable, in-order delivery of individual packets. HTTP is a stateless protocol, and it has a number of different requests that a client can use from a server.

Each request is sent as regular ASCII text, and the server responds with an object. The object returned can either be a simple Web page or a MIME response containing several objects, such as images. When fetching each object of a Web page separately, a new HTTP request must be performed for every object. Because of the high latency of those networks, fetching each part of a Web page with a separate request might cause significant delay. While this situation might not matter much when you are using a desktop computer that has a broadband connection, it is a significant advantage when you are developing for wireless networks.

File Transfer Protocol (FTP). Like HTTP, FTP is an application layer protocol. FTP is a connection-oriented file transfer between two hosts using TCP as transport. The only issue with FTP when running over wireless is greed. A client that fetches a file via FTP will start one TCP session and keep it throughout the transmission.

Before we get into the discussion of the different types of wireless networks/systems, Table 1 shows the comparisons between wireless and wireline network systems.

Cellular Phone Generation

The first radiotelephone service was introduced in the United States at the end of the 1940s, and was meant to connect mobile users in cars to the public fixed network. In the 1960s, a new system launched by Bell Systems, called "improved mobile telephone service" (IMTS), brought many improvements like direct dialing and higher bandwidth. The first analog cellular systems were based on IMTS and developed in the late 1960s and early 1970s. The systems were "cellular" because coverage areas were split into smaller areas, which are served by a low-power transmitter and receiver. See also **Telephony (Telecommunications)**.

First Generation (1G). First generation (1G) phones are analog. It sends information as a continuously varying waveform, and can only be used for voice and have highly variable call quality. The disadvantage is it is very insecure. Snoopers can listen in on call or charge calls to another person's account. Two key improvements were made during the 1970s — the invention of the microprocessor and the digitization of the control link between the mobile phone and the cell site.

Second Generation (2G). Second generation (2G) phones cover all speech into digital code, resulting in a clearer signal that can be encrypted for security. These systems digitized not only the control link but also the voice signal. The new system provided better quality and higher capacity at lower cost to consumers. It includes some kind of messaging, as well as support for Centrex-style services such as voice mail and caller ID. Most popular is GSM (global system for mobile communication), which can send data only at less than 10 Kbps (kilobits per second).

Second1/2 Generation (2.5G). Most operators are upgrading their 2G networks to higher data speed using fast modems. This term applies to technology such as WAP, which uses a compressed version of the Web to fit into a mobile phone's slow data rate and small screen. 2.5G networks, such as GPRS (global packet radio service), are already available in some parts of Europe.

Third Generation (3G). Third generation (3G) systems promise faster communications services, including voice, fax, and Internet, anytime and anywhere with seamless global roaming. The ITU's IMT-2000 global standard for 3G is expected to enable innovative applications and services (e.g., multimedia entertainment, infotainment and location-based services, among others). Instead of a phone, many terminals will be small computers or PDAs (personal digital assistants). It will cover not only the connection between a mobile terminal and its base stations, called a WAN (wide area network), but also the LAN (local area network). The vision behind it is mobile multimedia to all at the price of today's fixed telephony.

Fourth Generation (4G). Fourth generation networks are already in the labs, targeted for deployment beginning in 2010. It will provide data rates of up to 100 Mbps, enough for telepresence. This is a type of virtual reality, defined as full stimulation of all senses required to provide the illusion of actually being somewhere else — an illusion that cannot be distinguished from the real thing.

Cellular Networks

Cellular networks use many base stations, allowing them to cover a much wider area. The base stations are usually connected to each other using fiber optic cables to wireless links, then to external networks such as phone systems and the Internet.

A cell is the coverage area of a single base station. As a mobile phone moves through a network, it accesses services via the base station of whichever cell it is in. Radio waves radiate out from a transceiver. The further the mobile user is from the base station, the weaker the signal gets. The cell boundary is the limit where the mobile terminal can no longer send and receive reliably.

The overlap between cells also must be taken into account, as in some parts a user may be able to communicate with two or three base stations. One of the most important features of a mobile network is the ability for a user to move from one cell to another, originally known as roaming.

The process of switching a user from one cell to another while a call is in progress is called a handoff. Handoffs are very complex procedures because the base stations must calculate exactly when a user is crossing the cell boundary. This can take several seconds, so if users move too fast, their calls may be dropped.

The speed limit for analog systems is usually no more than 100 kph. Some digital systems can function at speed above 300 kph (on a high-speed train). No system can complete a handoff at the cruising speed of an airliner, one reason for not using a mobile phone on a plane.

Types of Handoff. There are three types of handoff:

Soft Handoff. Soft handoff ensures that a link is set up to the base station in the new cell before the old one is torn down. This system is very reliable. It should result in dropped calls only if the user is moving extremely fast or actually passes outside the cellular network. One problem is that a connection with two different base stations is very difficult to achieve. In most types of networks, adjacent base stations need to use different frequencies, while a phone can be tuned to only one frequency at a time.

Hard Handoff. Hard handoff requires that a phone break its connection with one base station before connecting to another. It is less reliable than soft handoff because a phone is not always able to establish a new connection. The new cell could already be full, or there may not be another cell available. A base station sometimes decides to make a handoff based on how far away a phone is, without considering whether another phone can pick it up. Hard handoff causes a noticeable break in conversation, which can be annoying for a user moving rapidly between small cells. To fix this problem, a network with microcell overlays tries to detect which users are moving and connects them to the main larger cell.

Effects of Frequency. The frequencies used by cell phones all lie within the UHF microwave band (same as used by TV transmission) ranging from 400 to 2000 MHz. Higher frequencies are more easily blocked by droplets of cloud in the atmosphere, which result in a shorter range. Networks based on these higher frequencies require smaller cells and more base stations. Lower frequencies initially seemed preferable because fewer base stations mean lower cost.

Voice Coding. All digital systems need to encode the analog waveforms of speech into a bitstream. The program used for this is called a codec

TABLE 1. COMPARISON OF WIRELESS AND WIRED NETWORK SYSTEMS

Wireless network
Transmission media
Radio, microwave, infrared and millimeter waves, lightwave/laser transmission
Twisted pair, coaxial cable, fiber optics
Standard
Wireless LAN: IEEE802.11
IEEE802.3 (based on Ethernet specification)
Wireless MAN: IEEE802.16
IEEE 802.5
Reference model
IEEE 802 reference model:
OSI reference model:
Physical layer
Physical layer
Data link layer (MAC sublayer, LLC sublayer)
Date link layer (MAC sublayer, LLC sublayer)
Upper layer protocols
Network layer
Transport layer
Session layer
Presentation
Application layer
Physical layer
Wireless LAN: Infrared, FHSS, DSSS, OFDM, HR_DSSS, OFDM
Thick coax, Thin coax, Twisted pair, Fiber optics
Wireless MAN: QPSK, QAM-16, QAM-64
Data rate
1–54 Mbps
Classical Ethernet: 10 Mbps
Fast Ethernet: 100 Mbps
Gigabit Ethernet: 1–10 Gbps
Fiber channel: 100 Mbps–3.2 Gbps
MAC sublayer protocol
CSMA/CA (combines CSMA and MACAW)
CSMA/CD
Random
Contention
MAC frame format
3 classes of frame: data, control, management Data frame format: frame control, duration, address1, address2, address3, seq., address4, data, checksum
Preamble (8 bytes), destination address (6 bytes), source address (6 bytes), type (2 bytes), data, pad (0–46 bytes), checksum (4 bytes)
Logical link control (LLC)
Run on top of Ethernet and other IEEE802 protocols. Hides the differences between the various kinds of 802 networks by providing a single format and interface to the network layer
Internet protocol
Mobile IP — Enable computer to maintain Internet connectivity while moving from one Internet
attachment point to another
Ipv4, Ipv6
Mobile IP basic ability — Discovery, registration, tunneling
Discovery
Use ICMP by adding the appropriate extensions to the ICMP header
ICMP
Routing algorithm
For mobile host: use foreign agent and home agent
Shortest path routing, distance vector routing, link state routing, etc.
In ad hoc network: AODV (ad hoc on-demand distance vector) routing algorithm
Congestion control algorithm
Poor performance. Since transmission link is unreliable, packets are lost all the time. The algorithm uses the wrong assumption (that timeout is caused by congestion) for congestion control.
Good performance Assume that timeout is caused by congestion, not by packet loss
Transport layer protocol
Poor performance using TCP Solution: Indirect TCP; makes modification to the network layer code in the base station
TCP
Datagram protocol
Performance is far from perfect using UDP. Since the transmission link is unreliable
UDP
WDP (wireless datagram protocol)

TABLE 1. (*Continued*)

Wireless network
Web application
Protocol stack
WAP — based on existing Internet standard, such as IP, XML, HTML, HTTP
HTTP/TCP/IP
— Application layer
Wireless application environment (WAE)
— Session layer (like HTTP)
Wireless session protocol (WSP)
— Transport layer (TCP)
Wireless transaction protocol (WTP)
— Like Netscape SSL
Wireless transport layer security (WTLS)
— UDP
Wireless datagram protocol (WDP)
— Physical layer
Bearer layer (GSM, CDMA, D-AMPS, GPRS)
Makeup language
WML, C-HTML, HDML, XML, WMLScript
HTML, XML, JavaScript
ATM network
Cell size
24-byte payload; header can be compressed and expanded to standard ATM
48-byte payload, 5-byte header
Media access control (MAC)
Problem: find suitable channel sharing/media access control technique at data link layer
CDMA
Data link layer
Needs to provide an error control, needs fragmentation, and reassembly
DHLC

(coder/decoder), often embedded within a special chip called a *digital signal processor*. Many different codecs are used in cell phones. The aim is to produce the lowest possible bit rate while maintaining acceptable sound quality. Because computing power is increasing continuously, new phones and networks are capable of using more advanced compression technology.

Waveform Coding. The simplest way to digitize a sound signal is to sample the waveform at regular intervals. This is called *pulse code modulation* (*PCM*) and is used by the DC and PSTN codec. A shorter interval will result in more accurate sampling but a higher bit rate.

Vocoding. Instead of sending an actual signal, a vocoder calculates how speech was produced and sends only the relevant pitch and tone information plus a description of the sender's mouth movements and vocal tract. A decoder then synthesizes a voice. Vocoders are used in a very low data rate situation. They can reach data rates as low as 1 Kbps.

Hybrid Codecs. Most codecs use a mixture of waveform and vocoding, based on synthesized speech with some PCM information. The precise bit rate depends on the quality of the sound and on how much processing power is available. For a mobile phone, the limiting factor is usually the need to compress and decompress in real time, using a battery-operated device. In any codec, there is a tradeoff between bandwidth and speech quality. Cellular networks typically use a codec between 5 and 13 kbps.

PCS Standards

PCS is any digital system that provides high-quality voice and narrowband data. It is the second generation of wireless technology, between analog cell phone and broadband mobile multimedia.

Three main categories of PCS are in use today. The first is the digital cell phones, which offer high-quality voice and limited data, the second category of PCS concentrates on data only, and the third category uses noncellular technologies in emergency services and large businesses. It works without a base station and supports automatic conference calls.

The largest category of PCS is used for digital cell phone networks. Although these were all designed primarily for voice, they can also support data transmission at varying rate. Most PCS systems are based on TDMA (time division multiple access), because FDMA (frequency division multiple access) is too wasteful of bandwidth, and CDMA (code division multiple access) had not yet been invented at the time they were standardized. The PCS system centers on spectral efficiency by how much capacity a system can squeeze out of its allocated frequencies.

GSM (Global System for Mobile Communication). Global system for mobile communication is an open, nonproprietary system that is constantly evolving. One of its great strengths is the international roaming capability. It is used by more than half of all mobile phones. It gives consumers seamless and the same standardized contact ability in more than 170 countries. GSM satellite roaming has extended service access to areas where terrestrial coverage is not available.

What is technically distinctive about the technology is that GSM differs from first generation wireless systems in that it uses digital technology and time division multiple access transmission methods. Voice is digitally encoded via a unique encoder, which emulates the characteristics of human speech. This method of transmission permits a very efficient data rate/information content ratio.

The system operates on four different frequency bands. It was originally designed for frequencies around 900 MHz, to reuse the spectrum intended for Europe's analog TACS networks. It was later adapted to 1,800 MHz, licensed in Europe specifically for GSM, and then to 1,900 MHz, used in America for several different digital networks. Like other digital cellular technologies, GSM encodes data into waves using a form of phase modulation, a system that uses the different parts of a waveform to represent information. The precise type is known as GMSK, which achieves a symbol rate and data rate of 270.8 Kbps in each of its 200-KHz channels.

HSCSD (High-Speed Circuit-Switched Data). HSCSD is a very simple upgrade to GSM that gives each user more than one time slot in the multiplex. All HSCSD-capable networks use the enhanced data codec, so that each channel allows a rate of 14.4 Kbps. The standard allows up to four of these to be tied together, for a maximum of 57.6 Kbps. Because of the overheating problem, most HSCSD devices are asymmetric, allowing greater download than upload speed.

GPRS (General Packet Radio Service). GPRS is the one most popular among operators of all the wireless Internet schemes. Designed for data, it promises to give every user a permanent and high-capacity connection to the Internet. GPRS represents a major step forward in mobile networks. Its key improvement is packet switching, which for most data application is more efficient than circuit switching. Packet switching uses bandwidth only when needed, freeing up gaps in the data stream for other uses. Because of this greater efficiency, the full specification calls for terminal scapable of using all eight time slots at once. The plan is that GPRS networks will eventually carry voice over packet, using a variable rate codec so the data can be transmitted during gaps in conversation.

D-AMPS (Digital Advanced Mobile Phone System). D-AMPS is designed to be compatible with older analog AMPS technology. It uses the 30-MHz frequency channel as AMPS, but divides each one up into three TDMA slots. D-AMPS uses the same-paired spectrum and structure as AMPS. The difference is that instead of sending a single FM radio transmission over a 30-MHz channel, it allows each one to be used by three simultaneous conversions. Operators of AMPS networks can selectively allocate channels to be either digital or analog, allowing the two systems to coexist. The modulation scheme is called differential quadrature phase shift keying (DQPSK).

PDC/JDC (Personal Digital Cellular/Japanese Digital Cellular). Japan has deployed a system based on D-AMPS, but designed for backward compatibility with its own J-TACS analog system. Despite being used in only one country, it is the world's second most popular mobile standard (behind that of GSM).

J-TACS used channels of only 25 MHz, which means that some changes were needed to the D-AMPS system designed for 30 MHz. The same size time slots and modulation are used, resulting in a lower overall bit rate. However, the D-AMPS voice codecs and data rate of 9.6 Kbps can still be achieved, by missing out some of the error correction and protocol overhead. This makes the system less reliable, but this problem can be overcome by keeping the cells small so that every user has a relatively clear link to the base stations.

D-AMPS+. D-AMPS+ is a scaled down version of GPRS that is implemented in the United States. When ETSI designed GPRS, they hoped that it could be applied to every TDMA-based system, including D-AMPS and PDC. The principle is simple — use more slots in the multiplex to increase the capacity until a single user has the entire channel all the time. GSM has eight time slots, while D-AMPS has only three, and each of these already offers a lower data rate of 9.6 Kbps compared to GSM's 14.4 Kbps.

One problem is that to achieve a faster rate, terminals need to be able to transmit and receive at the same time. A standard D-AMPS phone transmits for one third of the time, receives for another third, and is idle for the remaining third. Without simultaneous transmission and receiving, there is only one spare time slot (compared to six in GSM), limiting speed to only 19.2 Kbps in one direction and 9.6 Kbps in the other.

CdmaOne. CdmaOne is the only 20th century system to use CDMA. It was developed by Qualcomm, and it has been standardized by the Telecommunications Industry Association as IS-95a. CDMA systems seem superficially simpler than those based on TDMA. They involve no slot of frame structure. Every phone just transmits and receives all the time, sending many duplicates of the same information to ensure that at least one gets through. The very high transmission rate is achieved by using two different phase modulation techniques, quadrature phase shift keying (QPSK) on the downlink and offset quadrature phase shift keying (OQPSK) on the uplink. The second type required more forward error correction, because individual phones cannot coordinate their transmission in the same way that base stations can.

One large disadvantage of CDMA systems is their power consumption. By transmitting everything 64 times, a CdmaOne phone would seem to drain its battery 64 times faster than necessary and cover its user with 64 times as much microwave radiation. CdmaOne gets around this problem by carefully controlling the transmission power. The aim is to ensure that the signal strength at the base station is the same for every user, ensuring that all can be heard equally.

CdmaTwo. Phones based on CdmaOne already transmit and receive simultaneously and at very high data rates. Most of these data are redundant, but it doesn't have to be. A phone could use more than one of the available Walsh codes, multiplying its 16 Kbps capacity by any factor up to the number of calls per channel.

Third-Generation Standards

Third generation systems are critical to the wireless Internet services often touted as the future of mobile communications. They will offer permanent access to the Web, interactive video, and voice quality that sounds more like a CD player than cellular phone. The term 3G was originally defined as any standard that provide mobile users with the performance of ISDN or better, at least 144 Kbps. Technologically, the increased capacity is found in part by using extra spectrum and in part by new modulation techniques that squeeze higher data rates from a given waveband. Vendors, operator, and regulators all accept that the move toward higher data rates and better services will be evolutionary. Standards must be backward compatible with their predecessors so that phones can maintain a connection while moving between cells based on the old and the new.

IMT-2000. The third generation system was first planned in 1992, when the ITU realized that mobile communications was playing an increasingly important role. An international study group predicted that mobile phones would rival fixed lines within 10 years. It began work on a project called FPLMTS (Future Public Land Mobile Telecommunications System), aiming to unite the world under a single standard. The acronym was awkward, so ITU adopted the name IMT-2000. The number 2000 represents the year 2000, which the ITU wanted to make globally available for the new technology. The number 2000 also means the data rate of 2000 Kbps and the frequencies in the 2000-MHz region.

The ITU's original definition of IMT-2000 concerned only the data rate. Three different rates were suggested, each corresponding to a different type of ISDN, the standard for a carrier's core voice network. The first rate is 144 Kbps, which was the absolute minimum acceptable capacity. It is the same speed as a B-rate ISDN line, the type that can be deployed over ordinary telephone wires. B-rate ISDN makes up a large proportion of regular phone lines in some European countries. The second rate is 384 Kbps, which was the ideal capacity. It corresponds an H-rate ISDN channel, often used for videoconferencing. The third rate is 2 Mbps, which was the capacity that should be achievable inside a building. It corresponds to a European P-rate ISDN line, which is usually a fiber optic cable carrying up to 30 separate phone lines into an office switchboard.

Service Requirements. Just as none of 3G's 1992 founders foresaw mobile Web access, many of its ultimate applications may still not have been discovered. However, the industry is clear about its direction, and its goal is toward convergence: third generation's aim is to combine the Internet, telephones, and broadcast media into a single device. To achieve this, IMT-2000 systems have been designed with six broad classes of service in mind. Three of the service classes are already present to some extent on 2G networks, while three more are new and involve mobile multimedia. Here are the service classes in order of increasing data rate.

- Voice — Even in the age of high-speed data this is still regarded as the "killer app" for the mobile market. Third generation will offer call quality at least as good as the fixed telephone network, possibly with higher quality available at extra cost.
- Messaging — this is an extension to paging, combined with Internet e-mail. Unlike text-only messaging services built into some 2G systems, 3G will allow e-mail attachment.
- Switched data — this includes faxing and dial-up access to corporate networks or the Internet. With always-on connection available, dial-up access ought to be obsolete.
- Medium multimedia — this is likely to be the most popular 3G service. Its downstream data rate is ideal for Web surfing.
- High multimedia — this can be used for very high-speed Internet access, as well as for high-definition video and CD-quality audio on demand.

- Interactive high multimedia — this can be used for fairly high-quality videoconferencing or videophone, and for telepresence, a combination of videoconference and collaborative working.

Spectrums Requirements. In 1992, the ITU recommended that the entire world allocate the same frequencies to 3G services. This would enable easy global roaming, particularly if everyone was using the same IMT-2000 standard. Regardless of the location, the user could be sure that his or her mobile phone or data device would work. The only part of the 3G spectrums available worldwide is dedicated to satellite services. This problem is that while cellular 3G is only a year or two behind its original schedule, many analysts doubt that satellites capable of mobile 133-Kbps operation will ever get off the ground. Broadband satellites tend to need band now allocated to be released for cellular IMT-2000.

Compatibility. The ITU originally wanted a single global standard, but this has not been achieved. Instead, there are two main types of CDMA, and a third based on TDMA. The main reason for the dispute is compatibility with existing systems, which can be defined in three ways.

- Directed upgrades — Network operators without a license for new spectrum need to deploy a system that is essentially just an improvement of what they already have, so that new phones will work with the older base stations and vice versa. Upgrades typically add packet switching and better modulation, but keep existing cell size and channel structure.
- Roaming — In principle, a mobile terminal can be made to support any number of different systems, enabling them to be used worldwide.
- Handover — Roaming is inconvenient for most users, as phones must be reset to use a different network. To make it easier, a 3G system can be built so that it actually hands over users to a 2G network as they move outside its coverage area.

The fundamental problem for IMT-2000 is that no single standard could both upgrade CdmaOne and hand over to GSM. This means that two very similar CDMA-based IMT-2000 standards are set for deployment, and which one is deployed depends entirely on the local 2G systems.

W-CDMA. Wideband CDMA (W-CDMA) is the system favored by most operators. It has been designed to allow handovers to GSM; however, GSM network cannot be upgraded to W-CDMA, although some components, such as GPRS backbone, can be reused.

The wideband designation refers to the channel bandwidth of 5 MHz. This is 4 times that of CdmaOne, and 25 times that of GSM. A wider bandwidth was chosen to allow higher data rates, though only in uncrowded area with very clear reception.

TD-CDMA (Time Division CDMA). TD-CDMA (time division CDMA) sounds like a contradiction and is often referred to as a hybrid between TDMA and CDMA. The multiplex technique is CDMA, but time division duplexing is used to share a channel between uplink and downlink, making the most efficient use of spectrum as spare capacity not used for the uplink can be used for the downlink. TD-CDMA is not without cost in additional overhead, so W-CDMA operators tend to use it only for one channel, pairing the others off in the same way as other cellular systems.

UMTS (Universal Mobile Telecommunications Systems). UMTS has been the planned European W-CDMA standard since 1996. Its development was spearheaded by the UMTS forum, an industry and government group charged with developing a successor to GSM. The UMTS Forum succeeded in developing a draft W-CDMA proposal that was compatible with GSM, but it underestimated worldwide demand for mobile communications. Before a full UMTS standard could be tested and ratified, the proposal was picked up by the Japanese. The first W-CDMA networks are being deployed in Japan by NTT DoCoMo and J-Phone [Kaaranen, 2001].

CDMA 2000. Of the 2G systems, only CdmaOne is already based on CDMA. This gives it a head start in the race to 3G, as operators are able to upgrade their existing networks with new software of modulation rather than building a new radio system. These upgrades are collectively known as CDMA 2000; all are backward compatible with existing IS-95 systems. Until mid-2000, the upgrade path for CdmaOne seemed clear. The end result was supposed to be a system named CDMA 2000 3XMC. It combines three channels, resulting in a wider band. Unfortunately, this system was not compatible with the form of W-CDMA. In 2000, Motorola and Nokia together launched a system called 1Xtreme, which they claimed can reach speeds similar to that of 3XMC, but using only one channel, and hence a third of the spectrum.

EDGE (Enhanced Data Rates for GSM Evolution). EDGE (enhanced data rates for GSM evolution) is a technology based on TDMA. It was a planned upgrade for the GSM networks. The plan was that GSM operators would deploy it in their existing networks, while building UMTS to take advantage of the newly licensed IMT-2000 spectrum. Because UMTS can hand over calls to GSM, the two would even be compatible.

EDGE inherits almost all its main features from GSM and GPRS, including the eight-user TDMA structure and even the slot length of 0.577 ms. The only difference is the modulation scheme of 8-PSK, which triples the capacity compared to GSM.

EDGE could be applied to a regular GSM system, giving every user a landline quality voice or data connection, but it is such a major upgrade that every operator who installs it will also use GPRS and HSCSD. Because 8-PSK is more susceptible to errors than GSM, EDGE has nine different Modulation and Coding Schemes, each designed for a different quality connection.

To make EDGE deployment easier for a D-AMPS operator, the UWCC (Universal Wireless Communications Consortium) has defined a simplified stand called EDGE Compact. This can be used only for data, not voice, and so omits many of the control channels found in the full-scale system, which in the context of EDGE compact is referred to as EDGE Classic.

Finally, Table 2 summarizes the evolution of wireless systems.

TABLE 2. EVOLUTION OF WIRELESS SYSTEMS

1G systems
Established in late 1970s
Based on analog technology
Aimed at providing voice telephony service
Major technologies: AMPS, TACS, ETACS, NMT, JTACS, NTACS, NTT, C-450, RMTS, Radiocom
2G systems
Established in early 1990s
Based on digital and PCS technology
Aimed at providing a better spectral efficiency, a more robust communication, voice privacy, and authentication capabilities
Major technologies: GSM, TIA/EIA/IS-136 or D-AMPS, JDC, PHS, TIA/EIA/IS-95A, IS-54, PACS, CT-2, DECT
2.5G systems
Based on 2G Systems
Aimed at providing the 2G systems with a better data rate capability
Major technologies: GPRS, IS-95B, HDR, GSM/EDGE
3G systems
First planned in 1992, embodied by IMT-2000
Based on digital and PCS technologie
Supports hybrid air interfaces
Aimed at supporting multimedia services
Major technologies: UTRA, W-CDMA, UWC-136, IMT-2000, CDMA 2000, UMTS
4G systems
Developed in the labs, targeted for deployment beginning in 2010
Aimed at providing data rates of up to 100 Mbps

Mobile Data Services

Messaging. Every digital, and even some analog, mobile phone systems already incorporate some form of messaging. This allows subscribers to receive and sometimes send short text messages. This is essentially the same as paging, but with the data appearing on a mobile phone instead of a separate page.

In theory, messaging service should allow people to receive e-mail through their mobile phone and to dispense with pagers altogether. However, in practice, neither of these objectives has been achieved. Mobile phone operators are not geared up to deal with the type of services offered by paging companies. Most of the messages sent to a pager originate on the regular telephone network. To page someone, the user calls an operator, who transcribes the message and transmits it. Operators have

made more progress in interconnecting their own messaging networks so that customers of one operator can send messages to those of another.

A digital cellular phone uses three types of messaging services:

- SMS (short message service) — Only messaging standard to have achieved widespread acceptance. Began as part of the original GSM specification, but has since spread to all the other digital systems. Limited versions must be standardized for the AMPS and NMT analog systems.
- CBS (cell broadcast service) — If the same information needs to be sent to many different users, broadcasting is more efficient than transmitting a separate transmission. Each message is known as a page and can be only 93 bytes long. Up to 15 pages can be concatenated together. CBS has not been widely deployed because it offers operators no way to charge for the services.
- USSD (unstructured supplementary services data) — This service uses the control channel and can operate while a phone in use. The message is longer than that of SMS, with a maximum of 182 bytes. One advantage of USSD is it is connection-oriented. The network establishes a connection with the phone before sending any data.

The Wireless Web. Transferring the Web to cell phones presents several changes, including variable latency and input device design. Two issues that have preoccupied the mobile industry are low capacity and small screens. Most existing cell phone systems allow data speed of only 13.3 Kbps. Even more advanced technologies will push this up to 56 Kbps. Because of the small screen, many cell phones can display only a few lines of monochrome text, whereas a PDA has larger displays, but it still has limits. It is not possible to squeeze a desktop-sized screen into the palm of a user's hand.

C-HTML (Compact HTML). C-HTML (compact HTML) is a simplified version of HTML. As the Web became more focused on powerful computers with high-bandwidth connections, it was decided to create a special version of HTML for devices with limited computing power. It has only the core textual display language and simple graphics. The advantage of C-HTML is that it displays perfectly normal on any regular Internet browser.

HDML (Handheld Device Markup Language). HDML (handheld device markup language) is a more radical departure from HTML. HDML requires that a site avoid the use of tables, frames, flashing lights, and other complicated features. HDML replaces the familiar concept of Web pages with two new test layout metaphors called card and decks. A card is a single-user interaction, which would equate to a page in HTML. A single HDML file is called a deck because it can include many cards.

XML (Extensible Markup Language). XML (extensible markup language) is a code that lets Web authors define their own tags. This means that it can be used for any type of device that becomes Internet-enabled. XML provides more flexibility. Unlike HTML, it is not limited to the description built in the language.

Wireless LANs

The emergence and continual growth of wireless LANs are being driven by the need to lower the costs associated with network infrastructures and to support mobile networking applications that offer gains in process efficiency, accuracy, and lower business costs.

The implementation of wireless networks offers many tangible cost savings when performing installations in difficult-to-wire areas. If rivers, freeways, or other obstacles separate buildings you want to connect, a wireless solution may be much more economical than installing physical cables or leasing communication circuits. The deployment of wireless networking in these situations costs thousands of dollars, but it will result in a definite cost savings in the long run.

A problem inherent to wired networks is downtime due to cable faults. With wired networks, a user might accidentally break the network connector when trying to disconnect a PC from the network to move it to a different location. Wires and connectors can easily break though either misuse and/or normal use. An advantage of wireless networking, results from the use of less cables. This reduces the downtime of the network and the costs associated with replacing cables.

The installation of cabling is often a time-consuming activity. For LANs, installers must pull twisted-pair wires or optical fibers above the ceiling and drop cables through walls to network outlets that they must affix to the wall. These tasks can take days or weeks. The deployment of wireless networks greatly reduces the need for cable installations, making the network available for use much sooner.

Unfortunately, wireless LANs suffer from a fatal flaw — they are slow. The result is that wireless LANs have remained a niche, used only in environments such as warehouses, where mobility is essential.

Wireless LAN Standards. The main problem faced by early wireless LANs was that there were no real standards. Each company produced its own proprietarily systems. Many simply chose not to buy a wireless LAN at all, for fear of being locked into a single vendor's technology. Standards began to emerge in the late 1990s, but potential customers were again spoiled for choice. Most wireless LAN standards are spawned by either the IEEE or ETSI. Between them, they have produced at least six incompatible standards.

Table 3 gives a summary of the wireless LAN standards available.

IEEE 802.11. IEEE 802.11 was the first wireless LAN standard to be defined. It uses the same switching protocols as wired Ethernet, but gave up wire in favor of ISM radio. Just to make things more confusing, it is actually two standards in one, each employing an incompatible type of spread spectrum.

The simplest version of 802.11 uses a frequency-hopping spread spectrum, rapidly cycling between frequencies many times each second. It has 70 different frequencies to choose from, so while some may be blocked, another is clear. If information doesn't get through, it is resent. A more complex version uses a direct sequence spread spectrum (DSSS). It transmits on all frequencies simultaneously. This increases the data rate, but also uses more powers. See also http://www.ieee802.org/11/.

IEEE 802.11b. IEEE 802.11b is based on a DSSS version of IEEE 802.11. It uses a better modulation technique to increase capacity up to a maximum of 11 Mbps. As well as a large increase, this speed also pushes to match the original Ethernet standard.

IEEE 802.11a. IEEE 802.11a reaches a speed of 54 Mbps by abandoning ISM and spread spectrum. It uses the U-NII band and a technique called *coded orthogonal frequency division multiplexing* (OFDM), which is designed to minimize interference caused by a signal reflecting off walls.

HiperLan 1. HiperLan 1 was the standard proposed by ETSI in 1992, when it first recognized the need for high-speed wireless LANs. Much of it is based on Ethernet, although its radio access technology was taken straight from GSM.

HiperLan 2. HiperLan 2 uses the same spectrum as HiperLan 1, but is otherwise much closer to IEEE 802.11a. It has a maximum data rate of 54 Mbps, which is achieved by using the same coded OFDM technology.

HomeRF. HomeRF is designed for home networking. It is based on the original FHSS version of 802.11, and designed primarily for price rather than speed. Its major innovation is direct support for telephony. The other standards are all designed for data only, needing additional software to be able to carry voice.

Access Points. Wireless LAN systems can all be used for ad hoc networking between two or more users who happen to have a card installed. Areas such as offices or homes can also be fitted with access points, which both extend the range of the system and enable it to link to ordinary LANs or the Internet.

Private users can create their own miniature cellular network by setting up several access points. The entire standard includes a handover mechanism, similar to those of public cellular networks. The IEEE 802.11 family inherits the soft handoff system from CDMA cellular, meaning that the mobile unit tries to form a link with a new access point before it disconnects from the previous one. Hyper LAN systems use a hard handover similar to GMS, which means that they must disconnect from one access point before reconnecting to another. This is less reliable and results in a short interruption in connectivity.

Access points can take two forms, hubs and switches. A hub is the simplest, simply rebroadcasting everything it receives. A switch is more discriminating, sending transmission only to smaller subgroups known as segments. They improve network performance, as the total capacity is shared per segment.

On a wired network, there is no limit to the number of segments. A switch could put every user on its own segment, giving each access to

TABLE 3. WIRELESS LAN STANDARDS

Standard		Operating frequency	Data rate	Modulation	Functionality
IEEE 802.11	Infrared	Operating at a wavelength between 850 and 950 mm	Omni-directional; range is up to 20 m; 1 Mbps and 2-Mbps data rate	16-PPM (pulse position modulation)	Distribution service: association, disassociation, reassociation, distribution, integration
	FHSS	Operating in the 2.4-GHz ISM band	Make use of a multiple channels, with single hopping from one channel to another based on a pseudonoise sequence. Data rate is 1 Mbps and allows for optional 2Mbps	2-level gaussian frequency shift keying (GFSK) modulation for 1 Mbps; 4-level GFSK for 2 Mbps	Station service: eauthentication, deauthentication, privacy, data delivery
	DSSS	Operating in the 2.4-GHz ISM band	Use up to 7 channels, each with 1- and 2-Mbps data rates	Data rate of 1 Mbps for DBPSK and 2 Mbps for DQPSK	Designed to be mobile Ethernet
IEEE 802.11b		DSSS schema	5–11 Mbps	CCK	
IEEE 802.11a		Operating in 5-GHz band, support OFDM.	6, 9, 12, 18, 34, 36, 48, 54 Mbps	BPSK, QPSK, 16-QAM, 64-QAM	
IEEE 802.16		Operating at 10–66 GHz frequency range		QAM-64, QAM-16, QPSK	Designed to be wireless, but stationary. Supports heavy-duty multimedia usage.
IEEE 802.16a		Supports OFDM in the frequency range 2–11 GHz			
IEEE 802.16b		Operates in 5-GHz ISM band			
HiperLan 1		Provides up to 20-Mbps data rate in the 5-GHz range of the radiofrequency (RF) spectrum.	Can only use one channel	High-transmission rate: 24 Mbps, GMSK. Low-transmission rate: 1.47 Mbps, FSK	For ad hoc networking of portable device. Does not control or guarantee QoS on wireless link
HiperLan 2		Supports OFDM	Up to 54 Mbps data rate for short-range (up to 150 m) communication	BPSK, QPSK, QAM-16, QAM-64	Support asynchronous data and time critical services, efficient QoS, ATM cells. Typical application include offices, homes, exhibition halls, airports, train stations, and so on

the full capacity all the time. Wireless networks cannot do this, because each segment needs its own spectrum. However, they could make it much easier to reallocate machines between different segments, a task that usually requires rewiring. A wireless network can do this at the push of a button, or even automatically.

Wireless ATM

ATM has been advocated as an important technology for the wide area interconnection of heterogeneous networks. In ATM networks, the data are divided into small, fixed length units called cells. The cell is 53 bytes. Each cell contains a 5-byte header that comprises identification, control priority, and routing information. The rest of the 48 bytes are the actual data. ATM does not provide any error detection operations on the user payload inside the cell, and also provides no retransmission services, and only few operations are performed on the small header [Guizani & Rayes,1999].

There are some important factors that might help ATM make it successfully in the wireless world. These include flexible bandwidth allocation and service-type selection for a range of applications, efficient multiplexing of traffic from bursty data/multimedia sources, end-to-end provisioning of broadband services over wireless and wireline networks, and ease of interfacing with the wired networks systems that will form the telecommunications backbone.

Adoption of an ATM compatible fixed-length cell-relay format for PCN will result in a relatively transparent interface to an ATM backbone. By using ATM switching for intercell traffic, the crucial problem of developing a new backbone network with sufficient throughput to support intercommunication among large numbers of small cells is avoided. It is noted that for PCN micro- and picocells with relatively low traffic volumes, rather than direct connection to an ATM switch, it may be appropriate to use a lower cost shared media approach (such as TDM passive optical network or IEEE 802.6 optical bus) to interconnect several base stations.

Wireless ATM Key Issues.

Architecture. The wireless ATM architecture is composed of a large number of small transmission cells, called picocells. Each picocell is served by a base station. All the base stations in the network are connected via the wired ATM network. The use of ATM switching for intercell traffic also avoids the crucial problem of developing a new backbone network with sufficient throughput to support intercommunication among a large number of small cells. To avoid hard boundaries between picocells, the base stations can operate on the same frequency.

Reducing the size of the picocells has major advantages in mitigating some of the major problems associated with in-building wireless LANs. The main difficulties encountered are the delay due to multipath effects and the lack of a line-of-sight path resulting in high attenuation. Picocells can also have some drawbacks as compared to larger cells. There are a small number of mobiles within the range of any base station, so a base station's cost and connectivity are critical. Once the cell size is reduced, the handover rate also increases. By using the same frequency, no handover will be required at the physical layer. The small cell sizes also give the flexibility of reusing the same frequency, thus avoiding the problem of running out of bandwidth.

The mobile units in the cell communicate with only the base station serving that particular cell, and not with other mobile units. The basic role of the base station is interconnection between the LAN or WAN and the wireless subnets. It is also used to transfer packets and convert them to the wired ATM network from the mobile units. In traditional mobile networks, transmission cells are "colored" using frequency division multiplexing or code division multiplexing to prevent interference between cells. Coloring is wasteful of bandwidth since in order to be successful there must be areas between reuse of the color in which it is idle. These inactive areas could potentially be used for transmission.

Cell Size. The ATM cell size of 53 bytes is designed for 64 Kbps or higher, which may be too large for some wireless LANs due to low speed

and high error rates. Therefore, wireless LANs may use a 16- or 24-byte payload. The ATM header can also be compressed and be expanded to standard ATM at the base station. An example of ATM header compression is to use 2 bytes containing 12-bit VCI (virtual channel identifier) and a 4-bit control (payload type, cell loss priority, etc.).

One of the cell formats is to have a compatible payload size and addressing scheme, which should be different from the standard ATM cell format. Mobility should be as transparent as possible to the end-points, and therefore the VCIs used by the end-points should not change during handover. The allocation of the VCI should remain valid as the mobile moves through different picocells within the same domain. The translation of the VCIs should be as simple as possible due to movement between domains. This can be done by splitting the VCI space into a number of fields like domain identifier, mobile identifier, base station identifier, and virtual circuit number. A 16-bit CRC is also used to detect bit errors, due to the high error rate of mobile networks.

Physical Layer. The basic design issue for next generation private communication network (PCN) is the selection of modulation methods and a set of bit rates. A bit rate in the range of 5–10 Mpbs can be achieved using the existing wireless technologies, in a picocellular environment. Thus, with the exception of HDTV, most other ATM applications can be supported. The preferred technique may actually vary with the specific PCN application scenario to be addressed, so that it is likely that both TDMA and CDMA solutions will coexist. CDMA provides an efficient integrated solution for frequency reuse and multiple access, and can typically achieve a net bandwidth efficiency 2–4 times that of comparable narrowband approaches. However, a major weakness of CDMA for multiservice PCN is that for a given system bandwidth, spectrum spreading limits the peak user data rate to a relatively low value.

Narrowband (TDMA) can be used to achieve high bit rates. In a picocellular environment, using the narrow band approach can achieve a bit rate in the range of 8–16 Mbps. Overall, it should be possible for macro(5–10 km), micro- (0.5 km), and pico- (100 m) cells to support baud rates on the order of 0.1–0.25, 0.5–1.5, and 2–4 Msym/s, respectively. These rates should be sufficient enough to accommodate many of the broadband services.

Media Access Control (MAC). One of the major problems of wireless ATM is finding a suitable channel sharing/media access control technique at the data link layer. Shared media access leads to poor quantitative performance in wireless networks. When spread spectrum modulation is used, CDMA is the de facto mode of operation. Performance results from earlier studies shows that packet CDMA can achieve good traffic multiplexing efficiency and performance for CBR (constant bit rate), VBR (variable bit rate), and low-speed interactive data services, but CDMA is limited to less than or equal to 1 Mbps at higher speeds.

Data Link Layer. Wireless ATM needs a custom transparent data link layer protocol. A custom data link protocol is needed due to a high error rate and different packet sizes of wireless ATM. Wireless ATM may use a 16- or 24-byte payload, as 53 bytes may be too long for some wireless ATMs. The data link protocol may contain a service-type definition, error control, segmentation and reassembly, and handoff support.

A service-type field is needed so as to indicate whether a packet is of type supervisory/control, CBR, VBR ABR, etc. The service-type field simplifies base station protocol processing. Wireless ATMs should provide an error control due to high noise interference and poor physical level characteristics of the wireless medium. This is achieved using a PCN packet sequence number filed in the header along with a standard 2-byte CRC frame check sequence trailer. HDLC-style retransmission can be used for connectionless data.

Since wireless ATM may use 16- or 24-byte cells, segmentation and reassembly is required. As a handoff is an important characteristic of wireless networks, a soft handoff without any data loss is vital and should be transparent. This can be implemented by using bits in the header, which indicates PDUs before and after the handoff.

Future Phones

The wireless Internet industry is unsure about what type of devices people will want, or more accurately, what they can persuade consumers to buy. The consensus is around smart phones. There are two competing philosophies about the future of mobile devices:

- Personal area network — this assumes a modular system, whereby people continue to carry a plethora of devices as they do now. The difference is that all are linked together by a short-range radio system such as Bluetooth, with the cell phone acting as central hub and router.
- Integrated device — this assumes that people will want to carry only one device but vary it according to the situation. A user might want to travel light and use only voice communication. At other times, he/she will want to use a full feature computer with an internal high-speed wireless data connection. The mobile network automatically detects which terminal is in use and routes calls accordingly.

Wearable Computers. Anything smaller than a telephone will need a headset containing an earpiece and a microphone. For video on the move, several vendors have proposed putting tiny screens inside sunglasses or contact lenses. The latter has the potential to immerse users completely in virtual reality. The problem with any small mobile terminal is that its battery will quickly run down. Shoes can be used to contain a reasonable-sized battery.

Smart Phones. A smart phone is a mobile phone with some extra computer-type functions, like a WAP browser. Besides mobile data capabilities, smart phone features include location-based services and sophisticated address books that can interface with a computer.

Tablets. A tablet PDA is one that doesn't have a keyboard and relies on a touch-sensitive screen for input.

Clamshell. Before the arrival of large, touch-sensitive screens, nearly all PDAs use the same clamshell design as laptops.

Subnotebooks. Subnotebooks sit on the borderline between PDAs and full-fledged laptop computers. The first subnotebook was Atari Portfolios. It was designed to be IBM compatible, running MS-DOS.

WIREWORM *(Insecta, Coleoptera).* Slender hard-bodied larvae of the click-beetles. They live under bark and in logs or in the ground. Among the latter species are some important crop pests which damage the roots of grass and grains, and a few other crops including potatoes and cotton. The corn wireworm is one of the most widely known, often destroying entire fields.

The hard bodies of these worms render them immune from repellent substances that can be used in the soil, but crop rotation including clover, soy beans, buckwheat, flax, or some other species not subject to attack, is an effective method of avoiding serious loss.

WISHART'S DISTRIBUTION. The joint distribution of variances and covariances in samples from a multivariate normal population. It may be regarded as a generalization to p dimensions of the chi-square distribution, which is effectively that of the sample variance in univariate statistics.

WITCHES' BROOMS. The malformations known as witches' brooms are formed in many different kinds of woody plants. Many of them are caused by the presence of *Exoascus*, an ascomycete, which grows parasitically in the tissues of the plant. A bud infected by *Exoascus* is stimulated to rapid growth. So are the lateral buds of this shoot. The result is a bushlike mass of branches. The leaves of these infected branches are commonly dwarfed and fall earlier than the other leaves of the plant. The stems contain a much greater amount of parenchymatous tissue than is found in the normal branches. No reproductive parts are found on the brooms.

Witches' brooms are formed on fir trees; here they are caused by *Aecidium elatinum*, one of the rusts. A rust, *Gymnosporangium*, also causes the formation of witches' brooms on white cedars. Hackberry trees are often conspicuously covered with witches' brooms. In this plant they are caused by a mite, *Phytoptus*, which attacks the plant.

WITCH HAZEL. A small shrub or tree (*Hamamelis virginiana L.*) and considered a most unusual native plant. It was called *Oe-eh-nah-kwe-ha-he* (spotted stick) by the Onondaga Indians of New York, who used witch-hazel extract as a natural healer. The elixir was prepared by boiling the leaves of the plant. They also used the twigs to prepare a liniment for back pains. It has been reported that the early American pioneers used a snuff prepared from powdering dry witch-hazel leaves for stopping nosebleed. The fresh leaves of the witch hazel and twigs are still used for preparing an after-shave astringent and as an additive in some rubbing alcohols. The branches of the witch-hazel are fibrous and are well suited for making brooms. The witch hazel tree has the appearance of a twisted shrub whose branches zig-zag in all directions. Generally, the tree does not exceed ten feet (3 meters) in height. The tree habitually grows in the shade of tall trees in dense northeastern forests. Delicately scented flowers do not appear until fall when the shade of taller trees is removed. Flowers appear at an inopportune time for pollination — hence the tree has adapted itself to self-pollination. Also the tree's black seeds are ejected and thus do not require wind or any other natural assistance for distribution. The seeds may be "exploded" to a distance of nearly 50 feet (15 meters).

The record witch hazel tree growing in the United States is located in Bedford, Virginia. As compiled by the American Forestry Association, this specimen has a circumference (at $4\frac{1}{2}$ feet; 1.4 meter above ground level) of 52 in. (132 cm), a height of 35 feet (10.7 meters), and a spread of 30 feet (9.1 meters).

WITCH OF AGNESI. Let OBA be a circle with diameter $OA = 2a$ and let LK be a tangent to the circle at A. From O draw any line intersecting the circle at B and the tangent LK at C. From B draw a line parallel to LK and from C, a line perpendicular to LK. The intersection of these two lines is P and its locus is the plane curve called the witch. Its equation in rectangular coordinates is

$$x^2y + 4a^2y = 8a^3$$

and, if ϕ is a parameter, $x = 2a\cot\phi$, $y = 2a\sin^2\phi$. The curve is symmetric to the Y axis. Its asymptote is $y = 0$. See Fig. 1.

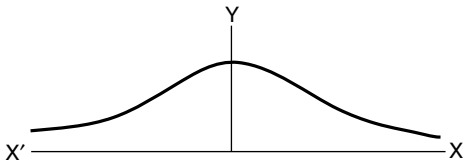

Fig. 1. Witch of Agnesi.

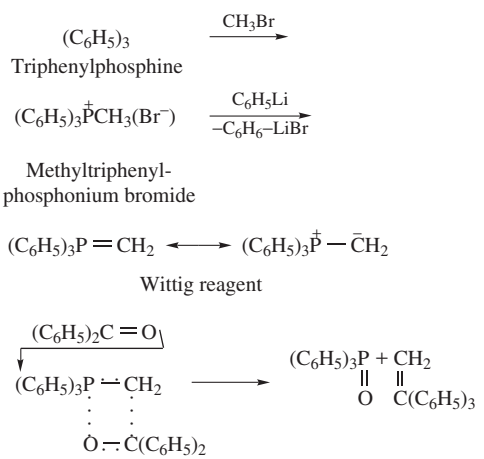
WITHERITE. The mineral witherite is barium carbonate [CAS: 513-77-9], $BaCO_3$, crystallizing in the orthorhombic system. It is interesting to note that at 811 °C (1492 °F) it changes to the hexagonal system, and at 982 °C (1800 °F) it appears to become isometric. It has a rather imperfect prismatic cleavage; uneven fracture; hardness 3–3.7; specific gravity, 4.29; luster, vitreous to resinous; color, white to yellowish or grayish; streak, white; transparent to translucent. Witherite is found in veins, and often is associated with galena, as at Alston Moor, Cumberland, England. Associated with barite at Freiberg, Saxony, and at Lexington, Kentucky. Named in honor of Dr. William Withering, an English botanist.

WITTIG, GEORGE (1897–1987). A University of Heidelberg professor who won the Nobel Prize for chemistry in 1979 along with Herbert C. Brown of Purdue. Wittig's research showed that phosphorous ylids react with ketones and aldehydes to form alkenes. This reaction is used a great deal in the synthesis of pharmaceuticals and other complex organic substances.

WITTIG REACTION. This reaction provides an excellent method for the conversion of a carbonyl compound to an olefin:



The reagent is unstable and so is generated in the presence of the carbonyl compound by dehydrohalogenation of the alkyltriphenylphosphonium bromide with phenyllithium in dry ether in a nitrogen atmosphere. There are various modifications, such as the phosphonate, in which diethylbenzylphosphonate, cinnamaldehyde, and sodium methoxide yield 1,4-diphenylbutadiene.

Dr. Georg Wittig, University of Heidelberg, was awarded the 1979 Nobel Prize for chemistry for his work in organic synthesis. Dr. Herbert C. Brown of Purdue University also participated in the joint award, but for separate work in organic synthesis.

More details on the early development of the Wittig reaction, dating back to the 1940s, is given in *Science*, **207**, 42–44 (1980).

WOHLER, FRIEDRICH (1800–1882). A native of Germany, Wöhler working along with Jöns Jakob Berzelius, placed the qualitative analysis of minerals on a firm foundation. In the early 19th century, chemists still thought it impossible to synthesize organic compounds.

Wöhler is regarded as a pioneer in organic chemistry as a result of his (accidental) synthesizing urea in 1828, which electrified the scientific community. Until 1828, it was believed that organic substances could only be formed under the influence of the vital force in the bodies of animals and plants. Wöhler proved by the artificial preparation of urea from inorganic materials that this view was false. Urea synthesis was integral for biochemistry because it showed that a compound known to be produced only by biological organisms could be produced in a laboratory, under controlled conditions, from inanimate matter.

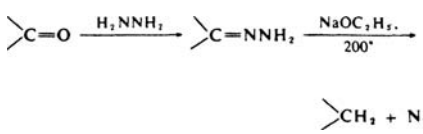
Wöhler was also a co-discoverer of beryllium and silicon, as well as the synthesis of calcium carbide, among others. In 1834, Wöhler and Liebig published an investigation of the oil of bitter almonds. They proved by their experiments that a group of carbon, hydrogen, and oxygen atoms can behave like an element, take the place of an element, and can be exchanged for elements in chemical compounds. Thus the foundation was laid of the doctrine of compound radicals, a doctrine which had a profound influence on the development of chemistry.

Wöhler's discoveries had great influence on the theory of chemistry. Journals from 1820 to 1881 contained contributions from him. The sum of his work is absolutely overwhelming.

WOHLWILL PROCESS. The official process of the U.S. mints for refining gold. It consists of subjecting gold anodes to electrolysis in a hot solution of hydrochloric acid containing gold chloride, the solution being continuously agitated with compressed air.

WOLF. See **Canines**.

WOLFF-KISHNEER REACTION. This method of reduction was discovered independently in Germany (Wolff, 1912) and in Russia (Kishner, 1911). A ketone (or aldehyde) is converted into the hydrazone, and this derivative is heated in a sealed tube or an autoclave with sodium ethoxide in absolute ethanol.



After preliminary technical improvements, Huang Minlon (1946) introduced a modified procedure by which the reduction is conducted on a large scale at atmospheric pressure with efficiency and economy. The ketone is refluxed in a high-boiling water-miscible solvent (usually di- or triethylene glycol) with the aqueous hydrazine and sodium hydroxide to form the hydrazone; water is then allowed to distil from the mixture till the temperature rises to a point favorable for decomposition of the hydrazone (200°); and the mixture is refluxed for three or four hours to complete the reduction.

WOLFRAMITE. The mineral wolframite, tungstate of iron and manganese, is an isomorphous mixture of tungstate of iron, $FeWo_4$, and tungstate of manganese, $MnWO_4$, the amounts being variable. The pure iron tungstate is called ferberite and the manganese tungstate, hübnerite. It has been proposed that the name ferberite be applied to mixtures of not less than 80% $FeWO_4$ and not more than 20% $MnWO_4$, and that the term hübnerite be given to mixtures of not less than 80% $MnWO_4$ but not more than 20% $FeWO_4$. Wolframite would thus include the minerals of intermediate composition, and its formula would be written $(Fe^{2+}, Mn)WO_4$. Wolframite is monoclinic, usually appearing in tabular, columnar or bladed crystals, sometimes quite large; also may be massive. Its hardness is 4–4.5; specific gravity, 7.371; color, gray, reddish-brown, brown or black; streak, reddish-brown to black; luster, submetallic; opaque, occasionally magnetic.

Wolframite is found associated with apatite, cassiterite, quartz, and fluorite; in granites and pegmatites. Often with scheelite, $CaWO_4$, and sometimes as a pseudomorph after that mineral. Wolframite is found in the Czech Republic and Slovakia, Rumania, Saxony, Cornwall in England, New South Wales, Bolivia; and in the United States at Trumbull, Connecticut; Luna and Lincoln Counties, New Mexico. It also occurs in small quantities in Nevada and Utah.

Ferberite, which has monoclinic tabular crystals, sometimes massive, resembles wolframite, and occurs in Spain and in Boulder County, Colorado. Superb crystals of Ferberite in association with apatite and arsenopyrite crystals occur at Panasqueira, Portugal.

Hübnerite crystals are monoclinic, often long fibrous or bladed, may be massive; resembles wolframite and is found in Peru, the Black Hills, South Dakota; San Juan County, Colorado; White Pine County, Nevada, and Lemhi County, Idaho.

WOLLASTONITE. The mineral wollastonite is calcium metasilicate, $CaSiO_3$, which is found as tabular or short prismatic triclinic crystals. This mineral has a hardness of 4.5–5; specific gravity, 2.87–3.09; color, white to gray, rarely green to colorless; luster, vitreous to pearly; transparent to translucent. Wollastonite in the main is formed by the action of contact metamorphic processes on limestones at relatively high temperature (600 °C+). Its common associates, diopside, vesuvianite, garnet and epidote, suggest this origin. Some of the more important localities are in the copper mines of Rumania, in the lavas of Monte Somma and Vesuvius, in Finland and Mexico. In the United States it is found in Essex and Lewis Counties, New York; Keweenaw County, Michigan; and Riverside County, California. Wollastonite was named in honor of the English chemist, William Hyde Wollaston.

WOMBAT. See **Marsupialia**.

WOOD. A vascular tissue which occurs in all higher plants. The most important commercial sources of wood are the gymnosperms, or softwood trees and the dicotyledonous angiosperms, or hardwood trees. Botanically, wood serves the plant as supporting and conducting tissue, and it also contains certain cells which serve in the storage of food. The trunks and branches of trees and shrubs are composed of wood, except for the very narrow cylinder of pith in the center and the bark which covers the outside. Botanists refer to wood by its Greek name, *xylem*.

A new cylinder of wood is laid down each year around the previously formed wood in the tree. This new growth originates in the cambium, a very narrow growing layer, which elaborates both the wood and the bark, and which separates these two tissues from each other. Each year's growth of wood forms a new concentric ring in the woody-stem, as viewed in cross-section. These are termed the annual rings. Each of these has an inner part (toward the pith) which is laid down in the early growing season and is termed the spring wood and an outer layer (towards the bark) which is laid down later and is known as summer wood. The cell walls of the latter are often thicker, forming a denser structure than the spring wood.

Most of the cells of wood are long, narrow hollow fibers and tubular-shaped cells arranged with their long axes parallel to the axis of the tree trunk. Certain food storage cells lie in radial bands, termed wood rays, which are perpendicular to the tree axis. The walls of this complex system of plant cells form the basic framework and material of all wood substance. All wood substance is composed of two basic chemical materials, *lignin*, and a polysaccharidic system, which is termed *holocellulose*. The latter embraces *cellulose* and the *hemicelluloses*, a mixture of pentosans, hexosans and polyuronides, and in some instances small amounts of pectic materials. Wood cell wall tissue also always retains small amounts of mineral matter (ash).

The outer portion of the cell wall, known as the primary wall, is heavily lignified. The intercellular substance, termed the middle lamella, is mainly lignin. The lignin of the middle lamella and primary walls thus serves as a matrix in which the cells are imbedded. Dissolution and removal of the lignin results in separation of the wood fibers. This is the underlying

principle in the manufacture of chemical pulps from wood for paper or other cellulose products. **Papermaking and Finishing**; and **Pulp (Wood) Production and Processing**.

About one-fourth or more of the lignin is in the middle lamella-primary wall complex. The remainder is within the holocellulose system of the cell walls.

Besides the cell wall tissue, which is the basic material of all wood substance, wood contains a variety of materials, many of which may be extracted by selected solvents. These extraneous components lie mainly within the cavities (lumen of the cells and on the surfaces of the cell walls. These "extraparietal substances" include a wide range of chemically different materials, such as essential oils, aliphatic hydrocarbons, fixed oils, resin acids, resinols, tannins, phytosterols, alkaloids, dyes, proteins, water-soluble carbohydrates, cyclitols, and salts of organic acids. The amount and composition of these extraneous substances vary greatly. The occurrence of certain of these substances is often very specific as to genera or species. Generally, however, the total amount of the extraneous components is only a few percent of the total weight of the wood.

The chemical composition of the extractive-free wood, i.e., the cell wall substance varies less than do the extractives. However, it is by no means constant, there being major differences between hardwoods and softwoods, and often between different genera and even between species. There is even some variability in chemical composition within the same log. For example, there is more lignin in the thinner-walled spring wood than in the summer wood, and more lignin in wood ray cells than in the tracheids or fibers. The heart-wood tissue often contains greater deposits of extraneous (extractive) components than the sapwood. There are major differences between most softwoods (conifers) and most temperate zone hardwoods (broad-leaf trees). Usually the softwoods have greater amounts of extraneous components extractable by organic solvents. Generally the lignin content of softwoods is higher than that of hardwoods, *viz.*, in the order of 25–30% compared to 17–24%. Also there is a major difference in the pentosan content between these two groups of woods, the hardwoods containing usually about 17–22% and the softwoods about 8–14%. There are exceptions to these generalizations, however.

The components of the cell wall substance of wood are exceedingly difficult to separate. Separations are rarely complete and generally bring about drastic chemical changes, especially in the lignin and molecular size degradation of the polysaccharides. To a considerable extent the components are apparently interpenetrating polymer systems. The long-chain linear polysaccharides tend to be parallel to the fiber axis and to form areas of varying degrees of crystallinity, as shown by x-rays and other physical and chemical properties. The lignin appears to be an amorphous tridimensional polymer.

Wood forms one of the world's most important chemical raw materials. It is the primary source of cellulose for the pulp and paper and cellulose industries. These industries are well up in the group of 10 major industries of the United States. For paper, rayon, films, lacquers, explosives and plastics, which comprise the greatest chemical uses of wood, it is the cellulose component (plus certain amounts of hemicellulose) of wood that is of value. The lignin forms a major industrial waste as a by-product of the paper and cellulose industries. Its major use is in its heat value in the recovery of alkaline pulping chemicals. A variety of minor uses for lignin have been developed, such as for the manufacture of vanillin, adhesives, plastics, oil-well drilling compounds and fillers for rubber.

Wood wastes from the lumber and woodworking industries form a great potential source of sugars and alcohol by acid hydrolysis of its polysaccharides followed by fermentation. Wood hydrolysis processes, however, are not yet economically competitive with other sources of sugars and alcohol in this country and many other areas of the world.

Wood is also an industrial source of charcoal, tannin, rosin, turpentine, and various other essential oils and pharmaceutical products.

WOODCOCK. See **Waders, Shorebirds, and Gulls**.

WOOD COMPOSITES. *Wood composites* can be defined as materials made by gluing together small pieces of wood, residue materials from wood processing operations, or other elements into larger materials to produce products with specific definable mechanical and physical properties. Wood composite products continue to be among the most widely utilized building materials throughout the world. They are commonly manufactured as lumber, flooring, roofing, paneling, palettes, decking, fencing, cabinets, furniture, millwork, structural beams, etc.

The increased number and importance of wood composite products are directly related to the decreased supply of high quality large timber, and as the quality and variety of wood composite products increases, and new applications for them are found, the trend toward increased use and importance of wood composites should continue. Wood composites offer numerous advantages over lumber. They can be produced from waste wood, agricultural residues, little used and low commercial value wood species, as well as smaller and fast growing trees, which can relieve stress on old growth forests that are increasingly unavailable for use. Also, the increased homogeneity of the raw material obtained by combining small wood elements allows a wide variety of composite products to be produced that have consistent, high quality properties. The properties can often surpass those of lumber (eg, have stronger and more uniform properties throughout the product, and be completely free of growth characteristics, weak spots, or defects such as knots), and often, the product can be produced with customized engineered properties, dimensions, and complex shapes (eg, complex roof shapes, cathedral ceilings, cantilevered supports).

The exact properties and the appropriate end use for a composite depend on the wood species and wood adhesive, and are very dependent on the size, shape, and arrangement of the wood in the composite. In fact, the names of the composite products are mostly based on the wood geometry (wood shape and size) and their arrangement in the product, without involving the name of the wood species or adhesive. These elements (species and adhesive) can be changed with far less effect on properties than changing wood geometry or arrangement.

The procedure for making a wood composite begins with the raw wood being processed by removal of leaves and bark, then being cut into pieces of the desired size and shape, followed by drying to the desired moisture content, and then going through a sorting process to ensure the wood pieces meet the selection criteria. This process is followed regardless of wood species or wood geometry. Some composite processes allow more than 90% of the tree stem to be utilized with either small or large diameter trees, while lumber can only be produced from large diameter trees and even then typically less than 50% of the tree can be converted to the intended product.

A large number of product types having quite different properties can be prepared using the same wood element. Processing conditions to convert the wood element into a composite product will depend on the type of adhesive selected and/or if the product being produced is pressed, impregnated, extruded, etc. Therefore, wood composites can be classified into two major types: (*1*) wood bonded with thermoset adhesives and (*2*) wood combined with other materials such as cement and thermoplastics.

Wood Bonded with Thermoset Adhesives

Wood composite products are conventionally manufactured from wood materials having various geometries (eg, fibers, particles, strands, flakes, veneers, and lumber) combined with a thermoset resin and bonded in a press. The press applies heat (if needed) and pressure to activate (cross-link) the adhesive resin and bond the wood material into a solid panel, lumber, or beam having good mechanical (strength and stiffness) and physical (form, dimensional stability, etc) properties.

Types of Wood Elements. A wide range of wood elements are employed to produce an increasing number of wood composite products. These elements can be broadly divided into two categories: "long grain" and "short grain" elements based on their size and shape. The largest of the commonly used long grain wood elements, excluding lumber itself, is veneer. Shorter grain elements include strands, flakes, wafers, particles, and fibers. It should also be noted that increasing numbers of wood composite products are employing recycled wood such as sawdust and wood flour,

which can be considered to be a separate wood type. Agrofibers are increasingly being employed as a raw material to produce commercial products similar to wood composites but with varying degrees of success. Some of the reasons for the rising interest in agrofibers include their low density and low abrasion, the potential to improve some properties such as stiffness, and potential cost savings when used as a filler for thermoplastics, and because many of these materials are the by-products of annual crops. In the United States and Canada wheat straw is currently the most important agrofiber furnish but many other agrofibers are of interest. Agrofiber preferences vary with availability and geographical region of the world. Soybean and cotton stalks, kenaf, flax, coffee and rice husk, hemp, fescue straw, ramie, and sugarcane bagasse are just some of the agrofiber raw materials being used or studied. Composites made from various agrofibers include low density insulating board, medium density fiberboard, hardboard, and particleboard. The mechanical properties for some agrofiber composites are reported in the literature, but additional research is needed, particularly on the long-term durability and weathering properties of these composites.

Thermoset Wood Adhesives

A wide range of adhesive types and chemistries are used to bond wood elements to one another, but relatively few adhesive types are utilized to form the composites themselves. The vast majority of pressed-wood products use synthetic thermosetting adhesives. In North America the most important wood adhesives are the amino resins, eg, urea–formaldehyde (UF) and melamine–formaldehyde (MF), which account for 60 by volume of adhesives used in wood composite products, followed by the phenolic resins eg, phenol–formaldehyde (PF) and resorcinol–formaldehyde (RF), which account for 32% of wood composite adhesives. The remaining 9% consists of cross-linked vinyl (X-PVAc) compounds, thermoplastic poly(vinyl acetates) (PVA), soy-modified casein, and polymeric diphenylmethylene diisocyanate (pMDI). Some products may use various combinations of these adhesives to balance cost with performance. See also **Amino Resins**; and **Phenolic Resins**.

Urea-Formaldehyde (UF) Adhesives. UF resins are produced in a two-stage condensation polymerization process through the reaction of urea with excess formaldehyde. In the first stage of the polymerization process, urea and formaldehyde are heated under slightly alkaline conditions (pH 7–8) to produce methylolurea resins. Depending on the synthesis conditions (eg, the *relative* urea-to-formaldehyde molar ratios, the reaction temperature, and pH), up to four molecules of formaldehyde can bond to urea owing to the four replaceable hydrogen atoms of urea. The methylolureas produced at this stage are low molecular weight prepolymer solutions that have no adhesive properties. During the second stage, these prepolymer solutions are slightly acidified, which causes the methylolureas produced in the first stage to condense with one another. As this occurs the prepolymer molecular weight increases, and as the polymerization of the UF resin advances further the growing chains begin to cross-link through the formation of methylene–ether links. At the desired point in this polymerization process the aqueous suspension of UF adhesive is neutralized, which stops the reaction before the resin precipitates, and cooled. Water is removed under reduced pressure (vacuum) to produce a final resin content of about 65% nonvolatile resin solids. The final stage of the condensation polymerization, which produces a solid cross-linked thermoset, is completed during production of the wood composite. It is accomplished by the addition of a small amount of acid catalyst to the UF suspension immediately prior to its application to the wood element and occurs during the pressing cycle to produce the wood composite.

UF resin is applied to wood furnish as an aqueous suspension. With the addition of a catalyst such as an acid, the curing can occur at room temperature in a few days, but most industrial processes employ high temperatures and ammonium salts to shorten the bonding cycle. In the presence of heat and catalyst, UF condenses into a cross-linked three-dimensional network of macromolecules that provide bonding. UF resin cures rapidly, provides strong adhesion in a permanently dry environment, and is the least expensive of the major wood adhesives. For these reasons, UF resin is by far the dominant commercial adhesive and is widely used throughout the world for bonding wood and wood-based composites. Despite these attributes, UF resins have three major drawbacks: (*1*) their brittleness once cured, (*2*) their limited resistance to moisture in the cross-linked state (limiting their use to interior products), and (*3*) the potential for formaldehyde emission from UF-bonded wood composites.

Melamine-Formaldehyde (MF) Adhesives. MF resins are produced by a condensation process by reacting melamine with excess formaldehyde. The reaction proceeds in a manner similar to that between formaldehyde and urea but progresses to a greater extent.

Cured MF resins are considerably more water-resistant than UF resins. This is attributed to the lower solubility of melamine in cold water compared to urea, and the overall greater hydrophobicity of the MF. These resins also have superior heat resistance and shorter curing times than UF resins because of the higher functionality of melamine compared to urea (up to six molecules of formaldehyde can react with melamine). Therefore, MF-bonded composites can be employed in both interior and in some exterior applications.

However, MF resins are costly (about 3.5 times the price of UF based on 100% resin solids), and can only be cured properly at high temperature, which adds to the cost. This is a serious commercial drawback.

As previously mentioned, MF and UF resins are often combined. In the case of UF resins it is done to improve their moisture resistance, to accelerate their cure rate, and to reduce formaldehyde emission from UF-bonded wood composites, while in the case of MF resins it is done to reduce the cost. However, because of the differences in reactivity between urea and melamine mixing these components can complicate the curing. The conditions needed to cure the MF can overcure the UF, and conditions designed to properly cure the UF can leave the MF component undercured. However, when a suitable cure cycle is found for the blended resin, a good combination of properties can be achieved.

Phenol-Formaldehyde (PF) Adhesives. PF resins are produced by the reaction of a phenol and formaldehyde. Depending upon the phenol-to-formaldehyde (P:F) molar ratios and the type of catalyst, two types of PF resins can be produced: resole and novolac PF resins.

Resole PF resins are produced by the reaction of phenol with excess formaldehyde (P:F molar ratio 1:1.8 to 1:2.2) in the presence of an alkali catalyst. Because resole resins contain reactive methylol groups, they are self-curing resins that can condense with active sites on the phenol rings to form a cross-linked network in the presence of heat even without additional hardener. Resole resins have a very branched structure and are by far the more important of the two types of PF resins for wood composites.

Conversely, novolac PF resins are produced by the reaction of excess phenol with formaldehyde (P:F molar ratio 1:0.8 to 1:1) in the presence of an acid catalyst. Unlike resole resins, novolac PF resins have a more linear structure and do not self-cure because they lack the residual reactive methylol groups of resoles. Therefore, an external curing agent such as hexamethylenetetraamine must be added to novolac resins to yield a cross-linked structure. Novalac PF resins cured under acidic conditions are not recommended for wood composites for long-term structural applications.

In the presence of heat and on the addition of sodium hydroxide (NaOH) or other catalyst, resole PF resins condense into a three-dimensional cross-linked network having reactive sites suitable for wood bonding. While too much heat accelerates the degradation of UF resins, use of heat is desirable in PF-bonded composites to achieve a high degree of cross-linking. It should also be mentioned that the curing rate of PF resins is strongly influenced by the amount of NaOH added to the resins, with the higher NaOH content affording a faster cure up to a point. However, use of an excessive amount of NaOH in PF resins has adverse effects, including increasing the affinity of the composite for absorbing moisture from the air, which in turn results in PF-bonded composites having a higher thickness swell. As is the case with UF bonding, the adhesion to the wood surfaces in PF-bonded wood composites is achieved through secondary and/or physical bonding. PF resins have greater moisture resistance and greater strength retention when exposed to a high moisture environment than UF resins, and so are employed extensively in the manufacture of wood composites slated for exterior applications. Long-term aging studies in which plywood specimens prepared using various adhesives bonds were exposed to natural weathering confirmed the superior moisture resistance of PF. The PF-bonded specimens retained up to 90% of their original strength even after 8 years, while the UF-bonded

specimens lost 100% of their original strength after only 4 years in service.

Resorcinol–Formaldehyde (RF) Adhesives. RF resins are a type of phenolic adhesive that are distinguished by a very high reactivity relative to PF resins. This greater reactivity is due to the two phenolic hydroxyl groups on resole. The groups *activate* one another by making each other more electron-rich. Therefore, the first hydroxyl group is much more reactive than the phenol hydroxyl group, and following its reaction the remaining hydroxyl group is still highly reactive. Consequently, although RF adhesives are generally prepared using excess resorcinol to produce a novolac-type resin, in contrast to PF novalacs, these resins set rapidly *with the addition of hardener* even at low temperatures (eg, anywhere from 5 to 70 °C (41–158 °F)). This is termed *cold curing*. The high reactivity between resorcinol and formaldehyde with additional hardener, eg paraformaldehyde, allows the cure to proceed rapidly to completion. The reaction can be further accelerated by applying heat. Attempts to produce a resole RF resin typically result in an unusable gel. Despite the ability to cure at room or elevated temperatures and give composite products having good moisture resistance, RF adhesives are not used extensively because they are among the most expensive of the thermoset adhesives, being second only to the isocyanates in cost. Nevertheless, RF adhesives are used as binders for selected wood products.

Isocyanates. Polymeric diphenylmethane diisocyanate (pMDI) is the most commonly used isocyanate wood adhesive mainly because of its lower volatility and toxicity when compared to other isocyanates such as toluene diisocyanate and dicylcohexylmethane diisocyanate. Some of the advantages enjoyed by pMDI include the fact that it is a liquid polymer, and so it does not require a solvent carrier for application, it is free of formaldehyde, and also it does not require acidic (the case with UF) or alkaline catalysts (the case with PF). It is an effective wood adhesive because the high reactivity of the isocyanate (-N=C=O) groups allows the resin to cure rapidly, and it has the potential to covalently bond directly to the wood by reacting with the hydroxyl groups on the wood surface.

pMDI forms covalent bonds and polar interactions with wood and tolerates both high moisture content in the wood and lower press temperatures during composite manufacture. When wood composites are prepared with equal amounts of adhesive and the bond strength and the dimensional stability of wood composites are compared it is found that pMDI's bond strength and dimensional stability of composites prepared with it are generally superior to those of amino and phenolic resins in both dry and moist environments. Despite these advantages, pMDI adhesives also have some disadvantages. There are some perceived health hazards associated with the manufacturing process, and it can bond to the metal surfaces of a hot press, which is undesirable, although this can be prevented by applying release agents to the surfaces of the press. However, the primary drawback is cost. pMDI is the most expensive of the wood adhesives.

Other Wood Adhesives. There is considerable interest in developing adhesives from renewable resources that can be used as a primary adhesive or as an adhesive component (an "extender") to replace a portion of petroleum-based adhesives. These natural and renewable resources include lignin, tannins, and natural oils such as soy bean and proteins.

Lignin. Lignin is a waste product produced in large quantities by the pulp and paper industry that is often burned as fuel. Lignin-modified PF resins have been formulated to bond fiberboards, strandboards, and structural plywood. Lignin is employed in this manner primarily to reduce the consumption of oil-based products and to a lesser extent for cost savings since lignin can be less expensive than phenols. The lignin is usually methylolated *in situ* during the PF resin formulation, replacing anywhere from 15 to 35% of the phenol. Some lignins (eg, lignosulfonates) have also been added directly into the adhesive formulation as a PF resin extender. Although lignin-based adhesives are used in bonding wood composites, these adhesives require longer press times, produce darker coloration of the panel, and potentially have lower strength relative to PF without lignin. However, composites having good dimensional stability and good performance under conditions of high moisture have been reported for boards produced with lignin-extended resins, so interest in developing these adhesives continues. See also **Lignin**.

Tannin. Tannin [CAS: 1401-55-4] is an inexpensive naturally occurring polyphenol found mostly in the bark of trees but also as a component of the wood of some species. Tannin, like lignin, has also been used as a substitute for phenol in the manufacture of PF resins. Although using tannin-based adhesives in the manufacture of wood composites is thought to have potential, some reports indicate that these resins have lower cohesive strength and lower moisture resistance compared to common exterior wood adhesives. The poor performance of tannin-based adhesives is attributed to their limited ability to cross-link into a three-dimensional network, their high initial viscosity, and a short pot life owing to the high reactivity of tannin with formaldehyde. However, extensive research has been conducted in recent years to improve the performance of tannin-based adhesives. For example, the addition of small amounts of amino or phenolic resins or metallic ion catalysts has been shown to effectively increase the degree of cross-linking, thereby improving the strength and moisture resistance of tannin adhesives. Reducing the pH or adding hardeners such as hexamethylenetetramine during resin formulation has been shown to decrease the initial viscosity of some tannin-based adhesives thus extending their pot life. These breakthroughs have allowed tannin-based glues to be used in the manufacture of wood composites in South Africa, New Zealand, India, South America, and to some extent in North America. See also **Tannin**.

Other adhesives such as hot melt adhesives (HMA), poly(vinyl acetate) (PVA, catalyzed or uncatalyzed), pressure-sensitive adhesives (PSA), or elastomeric adhesives (based on natural or synthetic rubbers) are also used in wood bonding. However, their use is mostly limited to nonstructural applications (eg, secondary manufacturing processes such as kitchen furniture, interior joinery, decorative paper, and packaging) where strength and water resistance are of limited concern.

Advances in Wood Composite Adhesives

Improvements in wood composite properties can be achieved in three areas: (*1*) improvements in wood properties, (*2*) improvement in adhesive properties, and (*3*) improvement in the overall wood composite design. Most advances in wood composites witnessed over the last 10–15 years have been brought about by improved manufacturing equipment and improved composite design (eg, oriented strandboard, I-joist, parallel strand lumber, and laminated strand lumber), while significant advances in future wood composites seem likely to involve changes in wood properties (eg, genetic modification to produce species with some desired property such as improved resistance to decay). However, given the importance of developing alternatives to petroleum-based materials, development of new adhesives may yield the next generation of significant advances in wood composite products.

Some of the more recent research efforts that may lead to new adhesive types are categorized as follows: (*1*) adhesives from natural products, (*2*) adhesives generated *in situ* in the wood, (*3*) adhesive modifications to facilitate processing, and (*4*) adhesive modification for improved properties.

Prior to the 1930s all adhesives were based on natural products (eg, proteins such as animal blood, casein, soy protein). Use of adhesives from natural products steadily decreased thereafter with the development of synthetic polymers that had superior properties. Recently, renewed interest has been shown in using natural products to replace, entirely or in part, petroleum-based adhesive components with natural products, without sacrificing the performance levels achieved with modern petroleum-based adhesives. The purposes are often to reduce cost and dependence on petrochemicals, to reduce formaldehyde emissions, and improve selected properties (eg, biodegradability).

Wood Composites Bonded with Thermoset Adhesives

The principal wood composite products currently in use in the United States and Canada are plywood, oriented strandboard, particleboard, medium density fiberboard, hardboard, hardwood plywood, and laminated veneer lumber.

Wood composites for structural and nonstructural applications that are bonded with thermosetting glues can be produced in many different geometries, including panels (3 ft or more in width by 3/8 to 1 in. thick), lumber (2 in. or more in width by 2–4 in. thick), or beams (3 1/8 in.

wide by 9 in. or more in depth). The exact procedure for making wood composites depends on the type of wood furnish (wood geometry), the desired arrangement of the particles in the final product, and the adhesive to be used, as well as the cure cycle if the adhesive needs to be reacted during the process step. These processing variables determine the characteristics of the final products, including mechanical properties, water resistance, dimensional stability, surface quality, and workability. Regardless of the increasing number of wood composite products being introduced into the market, the different sizes and shapes of these products, and the different volumes of these products that are produced, the fabrication process is a highly automated one, and once the adhesive mixture is applied to the wood furnish the general manufacturing method for preparing these composites is similar.

The composite fabrication process begins once the trees have been processed into a dried furnish and the furnish is transported to a device such as rotating drum (as is the case for flakes, particles, and fibers). Here, the adhesive and other additives are applied to the furnish by air spray, airless spray, or a high shear atomizer. The rotating drum possesses nozzles that are fed by hose lines connected to resin storage drums. Adhesive resin mixtures are applied to veneer-based wood products (plywood, laminated veneer lumber) by a roll coater, curtain coater, spray coater, or liquid or foam extrusion. The amount of adhesive applied to the furnish varies with the product and adhesive type. Common additives are also applied during this step and include wax (to improve dimensional stability by reducing moisture absorption), wood preservatives (for protection against insect and fungal attack), and fire retardants.

After resin application, the coated wood furnish moves to a forming apparatus. The forming apparatus arranges the furnish appropriately into a mat having the specified dimensions and orientation of wood raw material to give the desired product type with the desired dimensions and density after pressing. This mat is then prepressed to remove much of the air, ie, consolidate a loosely formed mat into a rigid mat which has a certain degree of cohesion to reduce its thickness. The formed mat then goes to a hot press where it is subjected to a selected press cycle. Here it is heated and pressed at the desired temperature and pressure for specified periods of time to bond the wood into a composite part of the desired thickness. The pressed wood composite finally goes on to the finishing steps where the panel is sized, sanded, trimmed to the desired thickness and dimensions, edge sealed, and packaged for shipment. In some cases the hot composite product is stacked to help retain heat and continue the cure out of the hot press, as is the case with phenolic resins.

The biggest differences in processing for each type of wood composite reside in the geometry and arrangement of wood furnish, the adhesive type and amount applied, and the cure cycle. The following sections describe the main characteristics of the major wood composite products made with thermoset adhesives.

Plywood. Plywood panels have been produced and marketed in the United States for more than five decades. They are considered a material of choice in the building industry because of outstanding structural performance as defined by a high strength-to-weight ratio, excellent dimensional stability, and durability compared to other building material. Plywood typically consists of an uneven number of thin layers of wood veneers, called plies, which are glued together into a panel. The individual plies are typically arranged in the panel so that their grains are perpendicular to one another (right angles of 90°). The plies are arranged at 90° to one another to improve the dimensional stability and make the properties of the plywood more uniform along both the vertical and horizontal axes. The anisotropic nature of wood results in a tendency to swell less parallel to the grain than perpendicular to the grain and simultaneously gives wood greater strength parallel to the grain than perpendicular to the grain. Therefore, arranging individual plies at 90° to one another affords greater dimensional stability, decreases the tendency to split, and generally evens out the strength properties in all directions. If the grain angles were not varied then the plywood would have less dimensional stability and be much stronger along the grain axis but weaker perpendicular to the axis. The appearance of the final product can be improved if desired by applying a decorative surface veneer to give the final plywood a desired appearance. The final overall properties of the plywood depend on many factors, including the wood species, the quality of wood veneers, the order of placement of the veneer plies in the panel, the type and amount of adhesive applied, and the curing or pressing conditions.

Both hardwood and softwood species are utilized in the manufacture of plywood. Softwoods (Douglas-fir, western hemlock, larch, white fir, ponderosa pine, redwood, and southern pine are examples) are generally preferred in construction applications where strength and stiffness are required. Hardwood plywood is generally preferred for decorative applications where appearance is most important and strength is a limited criterion, although hardwood plywood can also be designed for structural applications. In decorative applications, hardwood plywood often competes with thin MDF which can be given a high quality overlay giving it an appearance similar to that of hardwood plywood.

Oriented Strandboard (OSB). Oriented strandboard (OSB) panels have been developed as an alternative to plywood in building construction. The emergence of OSB was driven in part by a decreased supply of large diameter logs suitable for veneer production, and by innovation and productivity changes in the North American wood products industry over the past few decades as well as the structural performance of OSB products, which are suitable for use in most plywood applications but at a much lower cost. In addition, OSB manufacture allows small, low grade timber resources to be processed into a marketable product. This effectively saves raw materials that are in short supply and promotes efficient utilization of wood.

OSB panels are made up of rectangular strands (wafers or flakes) of wood approximately 0.030 in. thick, bonded together with exterior-grade adhesive under extreme heat and pressure to develop adequate strength properties in the panel. During this process, long grain strands are compressed and mechanically oriented more or less parallel to each other and arranged into three to five distinct layers. These layers are oriented at ca 90° to one another, ie, strands are aligned lengthwise in layers perpendicular to each other similar to veneer plywood. The strands near the surface are typically $\geq$ 3 in. long but shorter strands are sometimes used in core layers. The core layers are also sometimes randomly arranged rather than oriented. The strands for the faces are typically oriented parallel with the long direction of the panel, whereas the core layers are oriented perpendicular to the length of the panel. Hardwood species, alone or in combinations with softwood species, can be used in the manufacture of OSB panels, but preferably lower density wood species (eg, aspen poplar in the northern part of North America and southern yellow pine in the south) are employed because strands of these woods can be compressed into medium density boards with sufficient contact between strands during pressing for good bonding.

The alignment of strands and the use of long strands give OSB panels improved mechanical (strength and stiffness) and physical (dimensional stability) properties in the direction of alignment, which make them acceptable in a wide range of industrial, residential, and commercial applications. Even though OSB panels are being used as a substitute for plywood, their potential for use in some structural applications has been limited because of poor dimensional stability and durability compared to that of plywood. OSB panels will swell in thickness, and like all wood products decay when they come into extended contact with water. Since most of the thickness swelling is not reversed when the panels are re-dried, the products are regarded as unacceptable for some applications where high moisture contact is expected.

Particleboard. Particleboard is prepared using small dried-particles combined with a thermally curable adhesive or other suitable binder and bonded together under high heat and pressure into panels of the desired thickness. The raw materials used to produce particleboard consist of wood wastes from sawmills, primarily from milled or ground wood chips, sawdust, and planer shaving. In some cases recycled cellulosic materials and plant residues such as wheat straw and bagasse are utilized as furnish to make particleboard. Most particleboard is formed into flat panels. However, molded and extruded particleboard products such as furniture parts, molded door skins, and molded pallets are also produced.

Particleboard usually consists of a three-layered panel with two surface layers (outer layers) and one core layer (inner layer). The face furnish is usually thinner than that in the core. This permits the strength and stiffness of the panel to be tailored and the faces to be produced with smooth surfaces. The American National Standard for Particleboard, ANSI

A208.1, classifies particleboard by density, properties, and class, and is the voluntary particleboard standard for the North American industry.

Medium Density Fiberboard (MDF). MDF is manufactured from refined wood chips or other fine cellulosic materials combined with a synthetic resin. The adhesive coated furnish is joined together under heat and pressure to form a versatile material having varying characteristics depending on the composition and processing conditions.

The surface of MDF can be controlled so that it is smooth, flat, and uniform in appearance and free of wood growth features such as knots and grain patterns. MDF panels are highly valued by woodworkers because they machine well and are suitable for finishing operations such as direct printing (eg, wood grains), thin laminating (eg, paper, decorative foil laminates), and painting (eg, custom colors). These attributes allow MDF panels to serve as excellent substitutes for solid wood in many interior applications such as kitchen cabinets, furniture, door parts, and moldings.

Composite Lumbers and Beams. Composite lumbers and beams comprise a large and diverse family of products known as engineered wood products (EWPs). EWPs include laminated veneer lumber (LVL), laminated strand lumber (LSL), parallel strand lumber (PSL), glulam, and I-joists, among others.

LVL [also known as structural composite lumber (SCL)] technology was developed in Finland. Trus Joist became the first U.S. producer of LVL in 1970. LVL is a structural building material manufactured by layering dried and graded wood veneers with waterproof adhesive into billets of various thicknesses and widths. Generally, high quality laminates are used at the faces and low quality laminates in the center of the lumber. This specific arrangement gives LVL greater strength (by a factor of 2 or more) than conventional solid lumber having equivalent dimensions. In LVL billets, all veneers are laminated with the grain angle parallel to the longitudinal axis of the wood (one-grain direction) rather than arranging the veneer grains perpendicular to one another as in plywood. PF and pMDI are the resins that are typically employed to produce LVL and so the billets are hot-pressed or radio-frequency-pressed to consolidate the laminates. Common wood species used for LVL include Douglas fir, larch, southern yellow pine, and poplar, but other wood species can be used as the raw material. As an engineered wood product, LVL is an ideal structural building material for applications in housing, commercial, and industrial construction. Typical applications include floor and roof joists, roof beams, roof truss chords, flanges for prefabricated wood I-joists, concrete form, and scaffolding plank, among others.

Wood I-joists are hybrid beam elements that are made by gluing together lumber and panel composites to produce a dimensionally stable lightweight member having specified engineering properties. The product utilizes the geometry of the I-shaped cross section composed of two flanges (top and bottom) of various widths linked by a web (or two webs) of various depths. The flanges are typically LVL, or finger-jointed sawn lumber of various machine stress-rated grades, while the webs are either structural grade OSB or structural plywood. The flanges are designed to resist bending strength and provide stiffness, while the web is designed to resist shear forces in the beam. Thus, the I-shaped geometry of these products gives a high strength-to-weight ratio. I-joists are marketed as building products that do not warp, twist, or shrink, and their dimensions are more uniform than those of conventional sawn lumber joists. The wood I-joists performs much better than solid lumber because greater joist spacing can be used and their frames are lighter and more dimensionally stable than lumber, making their installation less costly for the builders. Wood I-joists are used in residential and light commercial construction in applications such as floor and roof joists, rafters, and purloins, among others. Wood I-joists are certified by the APA-Engineered Wood Association as the APA-Engineered Wood System (APA-EWS), and are manufactured in compliance with Performance Rated I-Joists (PRI-400), Performance Standard for APA-EWS I-Joists.

Glued laminated timber, or glulam, is a structural beam element manufactured by gluing laminates of solid wood lumber, finger-jointed lumber, or LVL. The individual lumber elements are oriented parallel to the longitudinal axis of the beam and laminated flat-wise to bond along the entire length and width of the lumber elements. Based on the stiffness rating of the individual laminations high quality laminates are generally applied at the beam faces, while low quality laminates are placed in the middle of the beam. This combination is preferred since the load is carried by the beam in the top and bottom faces, while the middle only has to resist shear. A cold curing resin adhesive such as resorcinol or phenol–resorcinol is usually used to produce the beam by applying the adhesive and clamping or cold-pressing the laminates. Since little or no heat is required for the cure, curved glulam members and other customized shapes can easily be produced. Glulams are manufactured in accordance with the American National Standards Institute (ANSI) ANSI standard A190.1 for structural glued laminated timber. The strength values (bending and shear) for glulam are higher than for lumber. Glulam members are typically used as headers, beams, arches, etc. The production of glulam is not expected to grow significantly in North America because of the scarcity and high cost of laminating grade lumber, combined with stiff competition from LVL and other engineered wood products such as LSL and PSL, which are expected to grow because they have excellent structural properties and they employ more readily available raw materials.

PSL is an engineered wood product developed by MacMillan Bloedel, Ltd., of Canada and was first commercialized in 1988. PSL is made in a similar manner to glulam beams with the difference being that strands of broken-up veneer (about 1/2 in. wide and up to about 37 in. long) are employed instead of solid lumber laminates. The strands are oriented and laid-up into a mat in a lengthwise direction, ie, aligned parallel to one another. The strands are glued with a water-resistant adhesive (PF) and are consolidated in a continuous microwave press. PSL is stronger, stiffer, and more stable than sawn lumber having the same cross section and is free of splits, knots, and warp. PSL is employed in various applications such as head beams, trusses, and other structural frames.

LSL is another type of engineered wood product in which all the strands are aligned in one direction, ie, LSL is an oriented strand lumber. The strands in LSL are shorter than in PSL and produced from strand wood rather than veneer. The strands are typically longer than strands utilized in oriented strandboard. Pressing includes steam injection rather than radio-frequency heating, and isocyanate resin is typically used rather than PF adhesive. LSL is used in industrial and light structural applications.

Wood Thermoplastic Composites

Wood-based composites continue to be among the most widely used building materials throughout the world. While thermoset wood composites date back to the early 1900s (a wood flour/PF composite called Bakelite®), wood combined with thermoplastic composites have become of major commercial importance only since the 1980s in the United States, although they have been in use longer in Europe. Wood-plastic composites (WPCs) represent a rapidly growing industry in the United States in both the plastic processors and forest products industries.

To plastic processors wood and other lignocellulosic fibers (eg, agrofibers) represent a vast supply of readily available raw materials for all types of WPCs. The inorganic materials enhance some composite properties (eg, strength and modulus) and are extensively employed as fillers, but have several drawbacks. They are produced from nonrenewable sources and they have high density, so products prepared with inorganic fillers tend to be heavy. Furthermore, these inorganic fillers cause equipment wear during processing. Therefore, on a volumetric basis, their use may not be very cost-effective. During the past two decades, wood fibers and other lignocellulosic materials have begun to penetrate the filled thermoplastic markets because they possess many advantages relative to the common inorganic fillers. These advantages include high specific stiffness and strength, easy availability, lower density, lower cost on a unit-volume basis, low hardness which minimizes wear of the processing equipment, renewability, recyclability, safety, and biodegradability. The replacement of inorganic fillers with lignocellulosic fibers also provides an opportunity to increase processing productivity rates.

The forest products companies, on the other hand, see plastics as a way to expand sustainable forest resource utilization through the use of wood waste, fibers from underutilized species, and reclamation and recycling of wood, other agricultural species and waste, and paper materials from municipal solid waste streams, as well as a way to make new construction materials with attributes that wood does not have.

WPCs are typically manufactured by first mixing dried cellulosic materials (in powder or fibrous form) with various plastics and other processing ingredients (eg, lubricants, fusion promoters, coupling agents, flame and smoke retardants, ultraviolet stabilizers). Cellulosic materials that are used in the production of WPCs include wood flour or particle, flax, jute, or other agricultural waste. The most commonly employed plastics are polyethylene (PE), polypropylene (PP), polystyrene (PS), and poly(vinyl chloride) (PVC). See also **Polyethylene**; **Polypropylene**; and **Polyvinyl Chloride (PVC)**. These thermoplastics are selected mainly because they can be processed at lower temperatures (150–220 °C (302-428 °F)) to prevent the degradation of cellulosic materials. Generally, wood flour and other coarse particles (10–100 mesh size) are easier to handle during processing than long fibers which tend to agglomerate and cause dispersion problems during mixing. However, because of their higher aspect ratio, long fibers provide greater reinforcing effects in WPCs than particles. The fiber can be difficult to disperse but the dispersion problems can be offset by using compatibilizers during processing. Once mixed, the blended material is processed into the desired shape by conventional plastic processing equipment such as an extruder, injection molder, and a hot press (compression molding). Most of the WPCs used in construction applications are extruded to a profile of uniform cross section (solid or hollow) and any practical length, whereas products having more complex shapes such as those used in the automotive industry or other consumer products are injection- or compression-molded.

WPCs comprise an emerging class of materials that combine the favorable performance and cost attributes of both wood and plastics. Because WPCs are true hybrid materials, they have strength and stiffness properties that are somewhere between both materials. They have outstanding bolt, drill, screw, and nail retention and they machine similarly to wood. Generally, WPCs are stiffer than neat plastics and have attributes that solid wood does not have. If properly manufactured, WPCs are more resistant to moisture (water absorption and thickness swell) than wood and resist attack by insects and fungi better than other wood products. This outstanding performance is due to the fact that the plastic matrix encapsulates the individual wood fibers, thus interfering with moisture uptake by the wood element. Moisture can only be absorbed into the exposed sections of the wood. WPCs can be sanded, stained, painted, and finished just like natural solid wood. However, sealants and paints are not required for protection because WPCs resist moisture better than wood, and WPC products can be prepared with colorants and other additives during the processing phase, which eliminates the need for additional finishing.

Because of their performance, easy installation, and cost-effectiveness, WPC products are being selected by homebuilders over other materials such as solid wood, concrete, clay, and aluminum, especially as building materials for applications like decking, siding, and window and door frames. WPCs are also used as molded panel components for automotive interiors. The market for these composites continues to expand in the United States and other parts of the world. Experts believe that the production of WPCs will continue to grow particularly because of their acceptance as a substitute for chromated copper arsenate pressure-treated lumber.

Although a variety of WPC products have been commercialized, some drawbacks in their properties may limit the market potential of these products. For example, WPCs are more brittle and have lower impact resistance than neat plastic products. In addition, their high density (62–85 lb/ft^3), which is almost twice that of solid lumber (22–40 lb/ft^3 for various pine species), may hinder their acceptance in the conventional structural lumber market. In general, unfilled plastics are more ductile than WPCs because the incorporated brittle wood fibers alter the ductile mode of failure of the matrix making the composites more brittle. The higher density of WPCs compared to the unfilled plastic and solid wood is mainly due to the compression of wood cell walls during processing. The final specific gravity of WPCs manufactured by injection molding, extrusion, and compression molding, even when made with a 0.9 specific gravity thermoplastic resin, is over 1 because the wood cell walls are crushed or compressed nearly to the specific gravity of solid wood without air spaces (approximately 1.5), and voids between and within the wood fiber structure are completely filled with resin.

Several attempts have been made to overcome the drawbacks of dense WPCs. Significant improvements in the impact strength of WPCs are achieved by incorporating impact modifiers into the formulation. However, impact modification of WPCs does not enhance their ductility or reduce the density of the products. The creation of a microcellular void structure (wood-like structure) in WPCs through foaming has recently been found appropriate to reduce the weight of the composites. The lightweight WPCs, as a result of the presence of microcells, exhibit enhanced ductility and impact resistance. However, the reduced density can be achieved at the expense of other mechanical properties such as strength and stiffness.

WOOD LOUSE *(Crustacea, Isopoda)*. Small terrestrial crustaceans of oval form, somewhat flattened. They live under bark and debris near the surface of the ground, in decaying vegetation, and in other sufficiently moist situations and are common in gardens. Also called sowbugs. These forms constitute the families *Porcellionidae* and *Oniscidae*, and in the closely related family *Armadillididae* are found the pill bugs. The latter are able to roll themselves into almost perfect spheres when disturbed. The numerous species vary in color from gray to brownish and blackish.

WOOD (or Timber; Lumber). The word wood is frequently applied to fuel, which, in this case, means forest products cut to a size suitable for burning in stoves. Again, especially in the plural form, the word refers to a stand of growing trees, especially if the stand covers a considerable area. The word may also apply to finished products such as boards, joists, and beams, all called wood. In botanical language, the word *wood* means: that part of the stem, trunk, or branches, which is composed of the water-conducting xylem and associated fibers, especially in perennial plants in which these cells form a considerable mass, as in trees, shrubs and vines.

The word timber is also applied to standing trees, especially in the phrase standing timber, meaning trees large enough to be commercially valuable. Another common phrase is timber-land. Timber also means prepared forests products, especially any large beams, or coarse products. Lumber has a similar meaning, but is used in a rather broader sense, applying generally to any forest products such as boards, planks, beams, etc.

Practically all plants yielding wood of any value are gymnosperms or dicotyledonous angiosperms. Among monocotyledons only certain bamboos and palms have any appreciable use, and that largely restricted to the regions in which these plants grow.

It is worthy of note that forests have a very great value to man in addition to their yields of wood. For a forest is a very important factor in conserving water, preventing it from rapid running-off, and so tending greatly to reduce the possibility of disastrous floods. This retention of water is due to several factors; one because the roots themselves tend to form hollows in which water stands and settles, to move slowly through the ground, another because the increased supply of humus accumulating in the ground under the trees acts as a sponge, absorbing and retaining water. Vast amounts of water are absorbed by trees and given off to the air by transpiration.

In North America, there are several types of forests, distinguished mainly by the kinds of trees most numerous in each type. In eastern North America, three main regions are recognized. There is the Northern

Forest, occupying the northernmost tier of states from Minnesota east, and reaching downward in the mountains to Virginia and Tennessee. The dominant trees of this forest are coniferous, with white pine the most valuable species. Other coniferous species are hemlock, fir, and spruce. Hardwoods such as oaks, maples and birches are important trees of this northern forest. The southern forest occupies the region bordering the Atlantic and Gulf of Mexico and extending from the southeastern corner of Virginia into the eastern part of Texas. This also is a forest dominated by coniferous trees, mostly species of pine. Hardwood trees of this forest include sweet gum, ash, and tupelo. Between these two forests and extending west into the prairie region is the hardwood forest, in which are found oaks, black walnut, hickory, and basswood. In the western half of the country there are two regions, one, the Pacific forest, occupying the states bordering the Pacific ocean, and composed largely of Douglas fir, redwoods and several species of pine, all trees frequently attaining tremendous size. Occupying higher elevations in the western mountain states in the Rocky Mountain forest, containing such trees as Douglas fir, Engleman spruce, several pines, aspen, red cedar, and many others. Including the southernmost tip of Florida and the southern borders of Louisiana and Texas is a forest of an entirely different type, the tropical forest. This is characterized by such trees as magnolia, and live oak with an undergrowth of palmetto, which occupies vast regions of land in Central and South America, as well as the West Indies. These tropical forests, or rain forests, occur through the lowland areas of the tropical regions of South America and Africa, especially along the great rivers. Their luxuriant vegetation is correlated with rainfall, as indeed are the location and development of the temperate hardwood forests and northern coniferous forests in both hemispheres.

Woods are divided into two main classes, softwoods and hardwoods, distinguished not so much by the nature of the wood as by the trees. Softwoods are those obtained from coniferous trees such as pines, spruces, hemlocks and firs; hardwoods come from deciduous trees, and include such trees as oaks, ashes, maples, basswood, poplars, gums, as well as many tropical trees. It will be seen that the relative hardness of the wood is not an indication of its classification, since many hard pines, which are softwoods, are much harder than the soft wood of the bass, the poplar and the tulip tree, all of which are classed as hardwoods. Softwoods are much more extensively used by man, being employed widely in building construction. Hardwoods are used for furniture, interior finish, and for products demanding special wood structure.

The structure of wood is a very important factor in determining its ultimate use. The woody tissue of any plant is composed entirely of cells or vessels of various kinds, the majority of them being elongated and thick-walled. In gymnosperms, from which come the softwoods, these cells are tracheids, elongated cells in the walls of which there are many pits. These tracheids vary in size and in the thickness of their walls; those which are formed during the season of most active growth, in the spring, being larger and having thinner walls than those formed later. The hollow center, or lumen, of the spring-formed wood cells is much larger than that of the summer wood. As a result of this variation in cell size and structure, the wood of the tree is made up of distinct concentric layers of cells, often very sharply distinct. These are the annual rings. By counting them one may obtain an accurate knowledge of the age of the trees. In addition to the tracheids there are in the gymnosperm wood other cells which extend in narrow radial bands outward towards the surface of the stem. These are the ray cells which collectively form the rays of the wood. In softwoods the rays are not conspicuous; in many they are very minute. In hardwoods the cellular structure of the wood is more complex. Tracheids are present and resemble those of the softwood in appearance. In addition there are many vessels. These are composed of many cells arranged in vertical rows extending considerable distances along the stem. It is characteristic of vessels that there is no cross wall separating the component cells. Pits are found in the lateral walls of the vessels. In hardwoods, there are also many fibers, slender elongate cells with thick walls, in which there are only a few small pits. Compared with those of softwoods, the rays of hardwoods are very large and often form a conspicuous feature of the wood. All these cells in both hard and soft woods are formed by the cambium cells. When first formed, all wood cells contain protoplasm. Very early in their development, the protoplasm of the vessels, fibers and tracheids is lost, the cell becoming void of any living contents. Only the ray cells, and any parenchyma cells that may remain, retain their protoplasm. Therefore, the greater part of the woody tissue of the tree is dead. For some time this wood functions, it being the region through which water and dissolved mineral matter passes up through the stem. Wood thus functioning is called sapwood. It is usually pale in color. As the stem increases in size, changes occur in the cells, and there is less and less ascent of sap. Their walls frequently become much darker in color; often the lumina of the cells becomes filled up with various solid substances. When this condition exists the wood is known as heartwood. The separation between sapwood and heartwood is usually quite distinct; it does not necessarily coincide with an annual ring, but may form a very irregular region. The appearance of the heartwood differs greatly in different woods; in some it is never distinct from the sapwood, in others it forms a small mass in the center of the stem, while in others it includes almost the entire stem. In color heartwood ranges from white through yellows, reds, greens, browns, and even black in different trees; often it is streaked and mottled with different shades of color.

The first step in the preparation of wood is cutting it into suitable dimensions. Usually this means that the felled trunks or boles, known as logs, are cut into lengths varying from 2 to 3 feet to 16 feet (0.6 or 0.9 meter to 3.8 meters) or more, depending on the use to which the wood will be put. These logs are then sawed into boards, planks, or larger pieces. The manner in which a log is sawed is often a very important factor in the value of the product, since many woods are valuable for their grain, which differs according to the way the wood is cut. The word grain, applied to wood, has many meanings. Commonly it refers to the appearance of the wood when finished. This is determined by the nature of the cells composing the wood and their arrangement. In many woods, especially the softwoods, the cells are all parallel so that the wood splits easily. Such wood is said to have a straight grain. In other woods, the cells are oriented in various directions. Such woods split with great difficulty, and are called cross-grained woods. Wood composed mostly of small thick-walled cells, with few vessels, is called fine-grained wood, in contrast to that having many vessels, usually of large diameter, known as coarse-grained wood. The rays of the wood often form an important feature of the grain, since when they are large they may appear in the form of distinct flakes or streaks in the surface of the wood. The size and appearance of these flakes are greatly changed by the method of sawing the wood.

The commonest way of sawing is called plain sawing. In this, successive boards or planks are cut from the log, beginning at one side and cutting successive pieces through the center of the opposite side. In those woods in which grain is of little value, especially those with very small rays, this method of cutting is entirely satisfactory, for it is quickly and easily done. In other woods, especially those in which the rays are large and form a conspicuous feature of the finished wood, it is not so satisfactory, since variation results. This variation is largely due to the nature of the rays, which extend directly outward from the center to the surface of the wood, and have little thickness compared to their other two dimensions. Consequently the first cuts will be across the rays, which will then appear as narrow linear streaks in the wood. When boards near the center are cut, the ray will be nearly parallel to the cut and so appear as an irregular broad patch on the surface, adding greatly to the beauty of the wood. Methods of cutting have been devised which increase the number of boards that show these radial cuts. These methods are known as quarter-sawing. There are many of these, all having as their object the cutting of the greatest number of radial cuts most economically. Another important feature of the grain of wood, which can be changed by the method of cutting, is found in the annual growth increment, which forms the annual rings of the cross section. In sawed woods these annual layers appear as lines or streaks, often elaborately twisting.

Another important step in the preparation of wood is drying or seasoning. This may be done either before or after the log is cut into boards. During this process much of the water present in the wood, both in the lumina of the cells and in the cell walls, themselves, is lost. As a consequence there is a certain amount of shrinkage of the wood, which is greater tangentially than in the other dimensions. As a result, the wood on drying tends to check or crack longitudinally, especially in large pieces of wood. For most purposes, undried wood, known as green wood, is entirely unsatisfactory; it

will twist, warp, and crack as it dries; it cannot easily be glued, or finished, and it is more subject to attacks of fungi and boring insects. There are two methods of seasoning woods. The older method was to pile the wood in such a manner as to secure the maximum exposure to air, separating each piece from the next by narrow strips of wood, or by other means, and leaving the piled-up wood to dry slowly. This is called air-drying or air-seasoning. To dry wood in this way requires a month or more for boards an inch thick and several years for very large sticks, especially if the wood be a hardwood containing much water. Naturally the climate greatly affects the time required, wet seasons causing very slow drying. Recently much of the wood used, especially that used in making furniture, interior finish, shingles, etc., has been dried artificially in large rooms heated artificially. By this method it is possible to dry wood in a few days instead of months or years. The product is also much drier and better fitted for use. This method is known as kiln-drying or kiln-seasoning. Properly prepared wood has the following properties that give it its special value. It possesses great strength and incompressibility, yet is flexible, giving without breaking, and elastic, recovering after bending. Many woods have special properties that particularly fit them for special uses.

The uses made of wood are so numerous that only those of the greatest importance can be named. Immense quantities of wood, both hard and soft, are used in the pulp and paper industry. In construction work other large quantities are used, and in a variety of ways. Poorer grades of lumber are much used in making forms in which concrete work is poured. Scaffoldings and other framework also use quantities of the cheaper kinds of lumber. Wood is still a most important material for the construction of dwellings and other buildings. For the framework and for the rough finish of the walls and floors, the poorer kinds of wood are mostly used. For the outer parts, such as shingles and clap-boards, and for the interior finish materials and floors, better grades, often of special kinds of wood, are used. Shingles, for example, are mostly cut from white or red cedar, which is very resistant to the weather. Floors are made from hard pine, from maple or oak, and a few other woods which do not splinter easily and which resist heavy wear favorably. Nearly all the woods used in construction work are softwoods, which are light in weight, durable and easy to work.

For cabinet work and furniture an entirely different group of woods is used. Most of these are hardwoods, selected for their fine grains, or for their color, or because fashion and the whims of fancy happen to give them popularity. Many of the woods used for this purpose are tropical woods difficult to obtain and so of great value. In early days furniture was made from solid pieces; later it became the custom to use thin pieces of wood glued to a background of a different wood. These thin pieces were called veneer. There were several reasons for using veneer. One of course was economy, since an expensive block of wood would yield many more pieces of veneer than it would boards. Another reason was found in the fact that it was often difficult to fashion things from the hard dense woods used. They would split or crack easily, whereas when glued to a more easily handled more suitable woods they became usable. Finally, and very important, was the fact that often veneers could be obtained showing a beautiful grain which could rarely be obtained otherwise. So veneering became important.

There are three ways of cutting veneer wood. They may be sawed like any board: this method is wasteful since much material is wasted in the cut, as sawdust; it cannot produce very thin pieces, and it does not give the best grain in many cases. An advantage is found in the high polish that may be given veneers cut by this method. A second method of cutting veneers is slicing. In this method the short piece of wood, called a bolt, from which the veneers are to be cut, is moved up and down against a heavy stationary blade. This method has an advantage over sawing in that it allows much thinner veneers to be cut. As in sawed veneers, sliced veneers are limited to the size of the bolt from which they are cut, which is frequently a factor against them. The third method and the one used in cutting nearly all the veneers in the United States, is rotary-cutting. In this method the bolt is revolved against the knife, the veneer coming off in a thin sheet of any width desired. In order that the wood may be more easily cut and the veneer handled better, the bolt from which it is to be cut is usually soaked in water or steamed for some time before cutting, by both the slicing and the rotary method. After cutting, veneers are pressed flat and dried, in which condition they may be held indefinitely. They are commonly glued to some hardwood when they are used.

Another way in which veneers are used is in the making of plywood. This is made by gluing together three or more layers of veneer, the grain of each layer being at right angles to the one above it. Plywood is very resistant to blows and not easily cracked or broken. For which reason it is much used in making boxes, table tops, crates, and panels designed for various purposes.

In addition to these major uses of wood, there are many others. Cooperage is one of these. There are two kinds, slack and tight, each producing a barrel or container suited for a special purpose. Slack cooperage produces barrels, kegs, tubs, etc., which are used as containers for vegetables, for nails, and for many other things. Quantities of wood are used in the manufacture of charcoal, which is extensively used in making steel, explosives, and carbon dioxide gas, and also as a filter in the manufacture of sugar. Charcoal is made by allowing a closely packed pile of wood to burn with insufficient air, as a result of which the volatile materials are driven off and the carbon of the wood left. Millions of cords of wood are used for fuel each year in the United States; much of this is waste wood, which would be of little value for any other purpose. Large quantities of light softwoods, especially basswood, are used in making excelsior; in this the wood is first scored and then stripped off in thin pieces by knives. Excelsior is largely used to pack around glassware and dishes, and as a stuffing for mattresses and upholstery of the cheaper grades. Other uses of wood are for railroad ties, poles, posts, and piling, all of which call for woods which may be treated in such a way as to resist rotting and the attacks of various animals.

The following woods have properties that particularly fit them for special uses. *Lignum-vitae*, the heaviest of all woods, is a dark, greenish-brown, fine-grained wood with an oily appearance. It is obtained from *Guaiacum officinale*, a small tree native in tropical America. The wood of another species, *Guaiacum sanctum*, is also used. Both trees have compound leaves and showy flowers borne in clusters in the axils of the leaves. The fine-grained wood with its much-crossed fibers is used in making pulley sheaves, and as bushing around the propeller shafts of steamships, as well as for bowling balls and mallet heads. The wood contains a resin, guaiacum, which was formerly highly esteemed as a valuable medicine used in the treatment of social diseases. Today it is of slight importance as a drug. Rosewood is obtained from *Dalbergia nigra* and other species, natives of South America. It is hard close-grained wood with a pleasant fragrance. It is much used as a cabinet wood. Sandalwood is obtained from trees native in the East Indian region. It is a firm-textured wood of dull yellow color, which darkens with age. Like rosewood, sandalwood has a characteristic aromatic odor. The tree, *Santalum album*, is interesting because it is a parasite on the roots of other plants. Satinwood is obtained from *Chloroxylon swietenia*, and other species, natives of India and Ceylon. The wood has a golden-yellow color and a brilliant luster, which makes it a valuable cabinet wood. Several species of walnut, particularly *Juglans regia* of Europe and Asia and *Juglans nigra* of North America, yield dark brown woods of great value. They are much used in furniture making, and in interior finish in houses, and also because, when once dried, they are not subject to any changes through swelling or shrinkage. They are particularly favored as material from which to make gun and rifle stocks. Walnut is capable of taking a very high polish. Another dark heavy wood which is much used in furniture making is ebony, the wood of *Diospyros Ebenum*, and other species. The sapwood of the tree is soft and creamy white and of little value; the heartwood is very dark, often black, and hard. There are many other less well known woods, which are frequently used in furniture making.

See also **Tree**.

WOODPECKERS AND TOUCANS *(Aves, Piciformes)*. In addition to woodpeckers and toucans, the *Piciformes* include the barbets, jacamars, and honey-guides. These birds are found in all parts of the world except the Australian region. Most species nest in holes in trees. In the woodpecker, the beak is adapted for chipping wood, and the feet are formed for gripping the bark of trees. The tail is composed of stiff feathers and is used as a brace against the surface to which the bird clings. See Fig. 1. Woodpeckers excavate deep holes in trees as nests and deposit white eggs, the shells of which are like translucent china. They also dig into decaying wood for the insects contained in it. Capture of insects is facilitated by the sharp

Fig. 1. Downy woodpecker. (*Cruickshank.*)

barbed tongue and sticky saliva. Both the barbed tongue and the stiff tail are lacking in a few genera.

Woodpeckers are well represented by numerous species, ranging from the diminutive piculets of South America and Asia to the great ivory-billed species, which attain a length of 18 inches (46 centimeters). North America has more than a score of species. The woodpecker's neck is so strong and its head so thick that it can withstand the vibrations set up for its chipping actions that no other bird could withstand. The woodpecker can beat against a tree at the rate of 20 pulses per second for nearly an hour at a time. The skull appears immune to this hard beating action. The cranium has been found to include a spongy shock-resistant tissue located between it and the beak. The tongue is about five times as long as the beak and is kept curled inside the mouth. Young birds cannot readily hold their heads up high because their heads are so heavy.

The wryneck is a bird related to the woodpeckers, but having soft tail feathers. The name stems from the curious habit of turning and extending the head displayed by the European species. The few known members of the group are found in Europe, Asia, and Africa. The flickers are moderately large woodpeckers of North America which differ from the other woodpeckers in their feeding habits. Flickers eat many insects on the surface of the ground and are particularly fond of ants, which they catch on their long sticky tongue. Three species are recognized: the common or yellow-shafted flicker, *Colaptes auratus*; the red-shifter, *C. cafer*; and the gilded flicker, *C. chrysoides*, of the southwest. Other species of the same genus occur in South America. The sapsucker is a North American woodpecker that cuts rows of small holes around the trunks of trees and visits them for the sap that exudes and for the insects that are attracted by it. The rows of holes are so regularly positioned as to be conspicuous. These birds are said to damage some trees seriously, causing the death of the tree in a few instances. The yellow-bellied sapsucker, *Sphyrapicus varius*, is the common eastern species. It is represented in the western United States by a variety, the rednaped sapsucker, and by two other species, the red-breasted and the Williamson sapsuckers, which occur in the far West. The jacamars are South American birds related to the woodpeckers. About the size of a robin, the jacamar is a slender bird with a chest of golden bronze and fiery red color. The beak is long and pointed and designed to catch flying insects. The feet are relatively weak and small. The jacamars drill cavities into tree branches for nesting. There are about 14 species in all.

Barbets are birds of several species intermediate between the woodpeckers and the toucans. They occur in the tropical regions of both Old and New Worlds, and some species are brilliantly colored. The name was formerly applied to other members of the order found in tropical South America, which are now known as puffbirds. The bill of the barbet incorporates bristles, which assist in catching insects. The coppersmith is a small Indian bird, *Xantholaema haematocephala*, a barbet with green coloring above and yellow-and-green markings below.

The toucan is a bird of South and Central America, characterized by an enormous beak. See Fig. 2. Most species are brilliantly colored and of large size. The beak, several times as large as the head, is of very light construction, with serrated edges used in cutting up fruit. The beak is covered with a thin horny shell and contains a fine bony reticulum. Toucans are also remarkable for their peculiar habit of tossing bits of food into the air and catching them in their mouth to be swallowed.

Fig. 2. Toucan. (*A.M. Winchester.*)

Honey guides are birds of several African and Oriental species. They lay their eggs in the nests of other birds and are named from their reputed habit of leading the way to nests of bees.

WOOD PRESERVATIVE. A material applied to wood to prevent its destruction by fungi, wood-boring insects, marine borers and fire. A common characteristic of these materials is toxicity to those organisms that attack wood, or in the case of fire retardants the ability to control combustion in terms defined by the Underwriters Laboratory. In addition, a satisfactory wood preservative must also (a) be capable of penetrating wood, (b) remain in the wood for extended periods without losing its effectiveness due to chemical breakdown, (c) be harmless to humans and animals, (d) be noncorrosive and, (e) be available in quantity at a reasonable cost. For certain uses, the preservative may be required to be colorless, odorless, nonswelling and paintable.

The principal wood preservatives in use today are classified as (a) preservative oils, (b) toxic chemicals in organic solvents, and (c) water-soluble salts.

The most important of the preservative oils is coal-tar creosote and its solutions in the form of creosote-coal tar and creosote petroleum. Coal-tar creosote is defined by the American Wood Preservers Association as — "A distillate of coal tar produced by high-temperature carbonization of bituminous coal; it consists principally of liquid and solid aromatic hydrocarbons and contains appreciable quantities of tar acids and tar bases; it is heavier than water and has a continuous boiling range of at least 125 °C (257 °F), beginning at about 200 °C (392 °F)." This material is one of the oldest wood preservatives and is regarded by many as the best substance known for protection against all forms of wood-destroying organisms. For normal service conditions, minimum retentions of 8–10 lb/ft^3(128–161 kg/m^3) of wood penetrated are sufficient. For extreme conditions, retentions as high as 35 lb/ft^3(561 kg/m^3) are desirable. Currently, coal-tar creosote and creosote solutions are used as preservatives for about 60% of all wood products treated.

Of the large number of toxic chemicals that are oil-soluble, only three are recognized by the American Wood Preservers Association and only one of these is a commercially important wood preservative, pentachlorophenol [CAS: 87-86-5] (C_6Cl_5OH). Although "penta" is effective against fungi and insects, it will not protect against marine borers, and hence cannot be used as a wood preservative for salt water installations.

The two most common solvents for carrying penta into the wood are a relatively high-boiling No. 2 fuel oil and a very low-boiling liquified petroleum gas, butane. When fuel oil is used it remains in the wood and although the end product is brighter and cleaner than creosote-treated wood, it has a somewhat oily character and cannot readily be painted. When LP gas is used as the solvent, the butane is recovered and the penta is deposited in the wood as a dry crystalline material, hence the wood retains its color and is readily paintable.

Water-borne preservatives are divided into two categories. One group which includes acid copper chromate, chromated zinc chloride, copperized chromated zinc arsenate and fluorchrome-arsenate-phenol is used where the wood is not subjected to excessive leaching. The second group, ammoniacal copper arsenite and three types of chromated copper arsenate which react to become practically water insoluble, are used at about 0.6 lb/ft^3(9.6 kg/m^3) when wood is placed in ground contact under severe service conditions.

Water-borne preservatives penetrate wood easily and the solution presents no problem in flammability or health hazards. Disadvantages of water soluble preservatives include the swelling and shrinking of the treated material, reduction in bending strength and stiffness as a result of failure to redry following treatment, and less protection against weathering and mechanical wear than provided by either preservative oils or oil soluble chemicals in which the solvent remains in the wood.

In addition to the general preservative categories discussed there is a fourth group known as "proprietary preservatives" which are composed of various combinations of toxic materials and solvents. These are sold under trade names and in some cases are protected by patents.

While wood preservatives can be applied by simple means such as brushing, spraying and cold soaking, well over 90% of all commercial wood treatment is by one of the "pressure processes." Although the details of the individual processes vary, the type of equipment and general procedure used are similar. Treatment takes place in closed cylinders 6–9 feet (1.8–2.7 m) in diameter and up to 180 feet (54 m) in length. The wood to be treated is placed in the retort, submerged in the preservative and subjected to pressures in the order of 200 psi (13.6 atm). The preservative is often at an elevated temperature and in some cases the wood is given a preliminary pressure or vacuum period prior to admitting the preservative into the retort.

The most satisfactory nonpressure process is known as "thermal" treatment. The wood to be treated is immersed in a preservative at an elevated temperature. This causes the air in the wood cells to expand so that when the wood is transferred into a preservative bath of lower temperature, the air contracts forming a partial vacuum and atmospheric pressure forces the liquid into the wood.

Although the fire retardant treatment of wood is essentially the injection of water soluble salts into the wood by pressure treating methods, it deserves separate mention if for no other reason than the higher salt retention (4 lbs/cu. ft. vs. 0.6 lbs/cu. ft.) (64 kg/m^3 vs 9.6 kg/m^3) required. Most fire retardant treatments are proprietary and are specified by the Underwriters Laboratory on the basis of flame spread ratings. The latter's list of building materials will give details of the ratings including those of a recently introduced leach-resistant fire retardant suitable for outdoor service. Common fire-retardant chemicals include diammonium phosphate, ammonium sulfate, sodium tetraborate and boric acid which are used in various combinations.

WILLIAM T. NEARN, Weyehaeuser Company, Seattle, WA

WOODWARD, ROBERT B. (1917–1979). An American chemist born in Quincy, MA, and widely regarded as one of the world's leading synthetic organic chemists. After receiving his doctorate from M.I.T. (the youngest student in the history of the institute to do so) he joined the Harvard faculty in 1937 as instructor and attained full professorship in 1950. He was recipient of the Nobel Prize in 1965 for his brilliant work in synthesizing complex organic compounds, among them quinine, cholesterol, chlorophyll, reserpine, and cobalamin (vitamin B_{12}). When he died in 1979, his synthesis of the antibiotic erythromycin was virtually complete, and finished by his associate's two years later. He was director of the Woodward Research Institute in Basel, Switzerland, and a member of the governing board of the Weizmann Institute in Israel.

WOOL. The natural, highly crimped fiber from sheep, wool is one of the oldest fibers from the standpoint of use in textiles. Minute scales on the surface of the fibers allow them to interlock and are responsible for the ability of the fiber to *felt*, a phenomenon responsible for felt cloth and mill-finished worsteds. Crimpiness in wool is due to the open formation of the scales. Fine merino wool has 24 crimps per inch (~10 per centimeter). Luster of the fiber depends upon the size and smoothness of the scales. The basic wool protein, *keratin*, comprises molecular chains that are linked with sulfur. When sulfur is fed to sheep in areas deficient of the element, the quality of the wood improves. Wool fibers that fall below 3 inches (7.5 centimeters) in length are known as *clothing wool*; fibers 3–7 inches (7.5–17.8 centimeters) long are referred to as *combing wools*. The wool-fiber diameter ranges from 0.0025 to 0.005 inch (0.06–0.13 millimeter). See also **Fibers**; and **Goats and Sheep**.

WOOLLY BEAR *(Insecta, Lepidoptera).* The densely hairy caterpillar of a moth of the family *Arctiidae*. Most hairy caterpillars belong to this family and most species of the family have hairy larvae.

WORD. An ordered set of characters that is the normal unit in which information may be stored, transmitted, or operated upon within a given computer. For example, the set of characters 11598 is a word that may give a command for a machine element to move to a point 11.598 millimeters from a specified zero. A *computer word* is specifically defined as a sequence of bits or characters treated as a unit and capable of being stored in one computer location. (*IEEE*.)

WORK. In the strict physical sense, work is performed only when a force is exerted on a body while the body moves at the same time in such a way that the force has a component in the direction of motion. In the simplest case where a constant force is applied in the same direction as the motion, it may be stated that work equals force multiplied by distance, or

$$W = Fs$$

An example could be the raising of mass m from elevation h_1 to elevation h_2 in a constant gravitational field where the acceleration of gravity is g. The work performed would be

$$W = mg(h_2 - h_1)$$

To generalize for more complex situations, the amount of work done during motion from point a to point b can be expressed by:

$$W = \int_a^b F \cos\theta \, ds$$

where F is the total force exerted and θ is the angle between the direction of F and the direction of the elemental displacement ds. In the cgs system, the unit of work is the dyne-centimeter or erg; in the mks system, the newton-meter or joule; and in the English system, the unit of work is the foot-pound.

In rotational motion, the foregoing definition can be exactly applied, but it is often convenient to express the force as a torque and the motion as an angular displacement. Thus, the work done will be:

$$W = \int_a^b \tau \cos\theta \, d\omega$$

where, in this case, θ is always the angle between the torque τ expressed as a vector quantity and the elemental angular motion $d\omega$, also expressed as a vector. The units of work performed in angular motion will, of course, be the same as in linear motion. It should be noted that the definition of work does not involve a time element. Power is defined as the rate at which work is performed.

WORK FUNCTION (Electronic). The energy (usually measured in electron-volts) needed to remove an electron from the Fermi level in a metal to a point an infinite distance away outside the surface. The work function is important in the theory of thermionic emission. In that case, as for example, that of an electron escaping from the heated, negatively charged filament of a vacuum tube, the work function may be called the thermionic work function. Photoelectric emission has a corresponding work function.

WORK HARDENING. Single crystals of pure metals show rapid plastic deformation at first, but this is often followed by a considerable increase in the shear strength. It is thought that this is due to the motion of dislocations along two different slip planes, which intersect and hence impede each other.

WORK (Virtual). When a system of particles subject to constraints is in equilibrium under the action of a set of impressed external forces, the total work done by these forces when the particles undergo small displacements compatible with the constraints (so-called virtual displacements) is zero. Analytically put,

$$\sum_{i=0}^{n} \mathbf{F}_{ie} \cdot \delta \mathbf{r}_i = 0$$

where the impressed external force on the ith particle of the system is $\mathbf{F}_{ie}$ and its virtual displacement is $\delta \mathbf{r}_i$. The sum is taken over all the particles.

WORLD GEOGRAPHIC REFERENCE SYSTEM (GEOREF). A geographic reference system for the world, used in the Air Force for aircraft position reports and target designation, and for the control and direction of air units engaged in air defense, air–sea rescue, and tactical air operations.

WORM. A word without exact scientific limitations. Applied to creeping animals of the invertebrate phyla with long slender bodies, but also to some flatworms with broad thin bodies and only inaccurately to worm-like forms such as some of the insects. Scientifically it embraces six phyla: *Platyhelminthes* or flatworms, *Nemertea* or ribbon worms, *Nematoda* or roundworms, *Acanthocephala* or spinyheaded worms, *Nematomorpha* or hairworms, and *Annelida* or segmented worms.

WORM GEARING. Screw gearing or worm gearing is used to transmit power between shafts with perpendicular, non-intersecting axes. The worm is usually of cylindrical form, and resembles a screw; a section through the worm thread shows that the teeth are straight-sided and analogous to those of an involute rack. Worms are cut on a lathe or a thread milling machine and are often ground and polished after cutting and hardening to obtain surface precision and finish.

The worm wheel is essentially a helical gear with a face curved to fit a portion of the worm periphery. See Fig. 1. The tooth from and shape are obtained by cutting the wheel with a special form cutter known as a *hob*, which is essentially a replica of the worm, furnished with longitudinal flutes to provide cutting edges. In cutting the worm wheel teeth, the hob and the wheel blank are rotated at a speed ratio exactly that of the finished set; the hob is properly located with respect to the plane of the wheel and fed in radially until the teeth have been cut to full depth. This cutting action generates worm wheel teeth that are of involute form at the midplane of the wheel, and are conjugate to the hob and consequently to the worm.

Tooth measurement in worm gearing is generally based on circular pitch, although diametral pitch gearing is manufactured and stocked by gear manufacturers. Circular pitch is measured in the diametral plane of the wheel and in a plane passing through the axis of the worm. If D_g represents the pitch diameter of the wheel, P_c the circular pitch, and N_g the number of teeth in the wheel, then

$$D_g = \frac{N_g P_c}{\pi}$$

The lead L of the worm is the distance that a thread advances in one turn, or the distance that a point on the pitch circle of the worm wheel will advance during one revolution of the worm. If N_w represents the number of threads or "starts" in the worm, then:

$$L = N_w P_c$$

A triple-threaded worm has a lead equal to three times the pitch; in a single-threaded worm the lead and pitch are alike.

The velocity ratio R of a worm gear set depends upon the lead of the worm and the pitch diameter of the wheel, or,

$$\frac{r/\min \text{Worm}}{r/\min \text{Wheel}} = \frac{N_g}{N_w}$$

Unlike most gearing, the velocity ratio is independent of the pitch diameter of one of the elements — the worm. The worm pitch diameter can therefore be selected to suit a particular center distance, or to make use of a stock hob and thereby dispense with the cost of a special cutter.

The lead angle H of the worm threads is the angle between a line tangent to the thread helix at the pitch line and a plane perpendicular to the axis of the worm. It is found from the following, where D_w represents the pitch diameter of the worm:

$$\tan H = \frac{P_c N_w}{\pi D_w}$$

The tooth pressure angle is measured in a plane passing through the axis of the worm, and is equal to one-half the thread profile angle A. Pressure angles of $14\frac{1}{2}^\circ$ are commonly used for single- and double-threaded worms, and 20° for triple- and for quadruple-threaded worms. However, in many modern worm gear reducer sets, pressure angles as high as 30° are employed.

The nature of the tooth engagement in worm gearing causes greater sliding action between the surfaces in contact than in the case of spur gearing. The amount of this sliding action varies with the helix angle, and affects the efficiency of the gearing although it contributes to the smoothness of the drive. Efficiency depends not only on the material of the worm and worm wheel, the amount and character of the lubricant, the velocity of rubbing, but also upon the size of the helix angle of the worm. The efficiency may be estimated from the following:

$$E, \% = 100 - \frac{R}{2}$$

The above expression refers to commercial worm gear reducers properly mounted and lubricated.

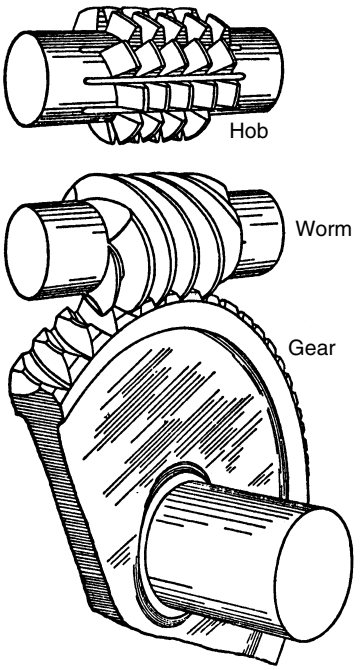

Fig. 1. Worm gearing and hob.

The power-transmitting capacity of worm gearing is based upon the strength of the teeth, the ability to resist wear and abrasion, and the heat-radiating capacity. Since the teeth on the gear are usually weaker than the threads on the worm, the design for strength and for wear is analogous to the method used for spur gearing. The heat-radiating capacity is a function of the efficiency and the square of the pitch diameter of the gear.

Worm gear sets should be carefully aligned in the axial plane of the worm, with the shaft axes at 90°. If the set is arranged so that the worm is underneath the wheel, the former may be run in an oil bath to insure adequate lubrication. Installations should preferably be enclosed to retain the lubricant and to prevent the admission of dust or foreign matter.

Globoidal worm gearing is a form of worm gearing in which a worm of "hour-glass" shape envelops a gear with straight-sided teeth. The capacity of this form of gearing is considerably greater than that of the conventional cylindrical type, and its efficiency is somewhat higher.

WRASSES *(Osteichthyes)*. Of the order *Percomorphi*, family *Labridae*, there are over 600 species of wrasses, all carnivorous. There is a wide variety of sizes, from 3 inches (7.5 centimeters) in length (pencil varieties) up to 10 feet in length and weighing several hundred pounds (*Cheilinus*). They are frequently of a brilliant color. Wrasses prefer tropical reefs or open temperate marine waters. Some of the larger wrasses are considered good food items. They are noted for their canine teeth and protactile mouth. Many wrasses are considered to be of vicious temperament. They do not regularly travel in schools. The sand burrowing habit is a rather distinctive characteristic of the wrasses. They are active swimmers in daytime hours, but at night like to bury themselves completely under sand. A number of species of the smaller wrasses have been identified as cleaner fishes, that is, fishes that remove ectoparasites from other larger fishes, usually carnivorous. It has been learned that the larger fishes tend *not* to devour the known cleaners because of the services which they render. A commonly occurring labrid is the *Tautoga onitis*, which attains a length of about 3 feet (0.9 meter) and frequents the American Atlantic coastal waters. The *Lachnolaimus maximus* (pudding wife) with a length of about 18 inches (45 centimeters) and the *Halichoeres radiatus* (pearly razorfish) with a length of about 15 inches (37.5 centimeters) also prefer these Atlantic waters. Of about 12 inches (30 centimeters) in length and found in the eastern Atlantic from the Mediterranean northward to Norway is the *Labrus ossifagus* (cuckoo wrasse). Also among the wrasses are *Gomphosus varius* and *G. tricolor* (birdfishes) which are found in Indo-Pacific waters. The long-jawed wrasse (*Epibulus insidiator*), equipped with an extremely elongated lower jaw, is known for its different color phases and is found in Indo-Pacific waters.

WREN *(Aves, Passeriformes)*. A small bird, related to the larger thrashers. Distinguished by its long curved beak and often sharply erected tail. Several species habitually build their nests about dwellings or in bird houses. From this habit the widely distributed and vociferous little house wren, *Troglodytes troglodytes*, has become widely known and the Bewick wren, *Thryomanes bewicki*, a more musical species, has introduced itself to many residents of the eastern states. The Carolina wren, *Thryothorus ludovicianus*, also frequents human habitations. North America is the home of a dozen species and Europe and Asia also have representatives of the group, but it attains its greatest diversity in South America.

WRIGHT, ALMROTH EDWARD (1861–1947). Wright was an English bacteriologist who pioneered the technique of inoculation against typhoid.

Almroth Edward Wright was born in Yorkshire on 10 August 1861. He was educated at Trinity College, Dublin, and graduated with a medical degree in 1883. He then went to Germany to study pathology under Julius Cohnheim and Carl Weigert.

On his return he studied law, and later entered the civil service as a clerk for the Admiralty. After a spell working at the University of Cambridge, then at the University of Sydney, Australia, he was, in 1892, appointed Professor of Pathology at the Army Medical School, based at Netley, Southampton, UK. It was here that he began work on infectious diseases, notably typhoid. Stimulated by W. M. W. Haffkine's work on cholera, Wright developed antityphoid inoculation. For this he was knighted in 1906.

In 1902 Wright became Professor of Pathology at St Mary's Hospital, where he remained until 1946. Here he established a centre for vaccine therapy; the aim was to use vaccines to treat, rather than prevent, infection.

During World War I Wright served in France, undertaking research into the pressing problem of wound infection. He was highly critical of the antiseptic method for cleansing wounds, pioneered by Joseph Lister. This was typical of his uncompromising attitude to research, and his love of controversy. His collected papers on wound treatment were brought together in 1942.

Wright influenced a generation of bacteriologists, among them William Leishman and Alexander Fleming. He wrote widely on nonmedical topics such as philosophy and votes for women. See also **Fleming, Sir Alexander (1881–1955)**, and **Leishman, William Boog (1865–1926)**.

CLAIRE E.J. HERRICK, London, UK

WRIST. The slender part of the forearm at its attachment with the hand, especially the region containing the group of small carpal bones between the radius and ulna of the arm and the metacarpals of the hand. See also **Ganglion**.

WRONSKIAN. Let $y_1, y_2, \ldots, y_n$ be functions of x, each having non-vanishing derivatives $y_i, y_i, \ldots, y^{n-1}$, then the Wronskian of the function is the determinant

$$W = \begin{vmatrix} y_1 & y_2 & \cdots & y_n \\ y_1' & y_2' & \cdots & y_n' \\ \cdots\cdots\cdots & & & \cdots \\ y_1^{(n-1)} & y_2^{(n-1)} & \cdots & y_n^{(n-1)} \end{vmatrix}$$

If $W = 0$, the n functions are linearly dependent; if $W \neq 0$, they are linearly independent. When the y_i are solutions of a linear differential equation of nth order, evaluation of the Wronskian is a simple means for deciding whether or not the n functions give the complete solution of the differential equation.

See also **Determinant**.

WROUGHT IRON. A ferrous material aggregated from a solidifying mass of pasty particles of highly refined metallic iron, with which, and without subsequent fusion, is included a minutely and uniformly distributed quantity of slag. This definition of wrought iron indicates that it is a material made of two components; one, iron of a high degree of purity, the other, slag (chiefly silicate of iron). In the finished product the slag is distributed through the iron in threads and fibers, of which there is an enormous number. The slag imparts to the wrought iron a fibrous structure, quite different from the crystalline structure of cast metals. Wrought iron has made for itself a name as a metal which has resistance to corrosion, and which is exceptionally suitable for structural purposes where the structure is subject to shock. Wrought iron also can be readily worked, forged, machined, welded, galvanized, etc. Among the many applications of wrought iron might be mentioned tubes, pipes, and tanks.

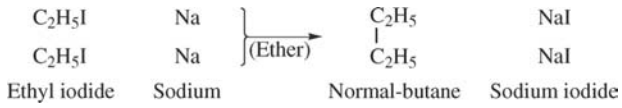
WRYBILL. See **Waders, Shorebirds, and Gulls**.

WRYNECK. See **Woodpeckers and Toucans**.

WULFENITE. The mineral wulfenite is lead molybdate [CAS: 10190-55-3] corresponding to the formula $PbMoO_4$, analyses showing that a part of the lead may be replaced by calcium. Wulfenite crystallizes in the tetragonal system usually in thin tabular forms, but is also found massive. It is a brittle mineral; hardness, 2.75–3; specific gravity, 6.5–7; luster, adamantine to resinous; color, yellowish to green or red, may be whitish or grayish; transparent to translucent. Wulfenite is a secondary mineral found in association with other lead minerals such as galena, and pyromorphite. It is believed to have been formed, at least in part, by the action of waters containing molybdenum salts on cerussite, anglesite, and pyromorphite.

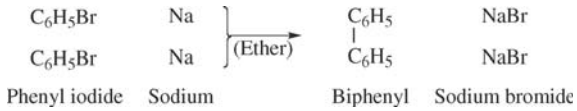
Especially important localities are in the former Yugoslav Republics, the Czech Republic and Slovakia, Morocco, Zaire, New South Wales and Mexico. In the United States it has been found in Phoenixville, Pennsylvania, and in the Organ Mountains, New Mexico; Yuma County, Arizona; Box Elder and Salt Lake Counties, Utah; and in Clark and Eureka Counties, Nevada. Wulfenite was named in honor of F.X. von Wülfen, an Austrian mineralogist of the eighteenth century.

WÜRTZ-FITTIG-FRANKLAND REACTION. Sodium metal was used by Würtz as reagent for the preparation of paraffin hydrocarbons by treating alkyl iodide in ethereal solution, thus:

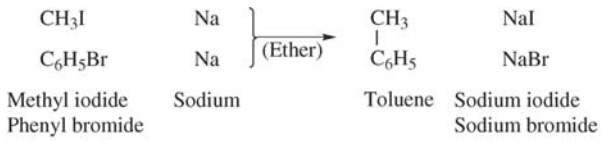


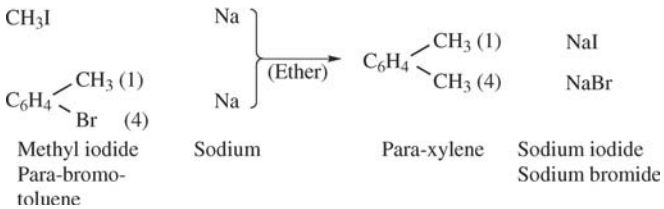
The method has been applied to the preparation of paraffin hydrocarbons as high in the series as hexacontane [CAS: 7667-80-3] $C_{60}H_{122}$. The alkyl radicals may be the same or different in the iodide or iodides taken.

Sodium metal was also used similarly by Fitting as reagent for the preparation of hydrocarbons by treating aryl bromide or iodide in the presence of dry ether, thus:



When alkyl iodide and aryl bromide are taken, the hydrocarbon is of the mixed alkyl-aryl type, thus:





The method has been applied to the preparation of substituted benzene hydrocarbons containing as many as four alkyl-groups (durene [CAS: 95-93-2], $C_6H_2(CH_3)_4(1,2,4,5)$ and isodurene [CAS: 527-53-7], $C_6H_2(CH_3)_4(1,2,3,5)$).

Frankland introduced the use of zinc instead of sodium to accomplish similar reactions. See also **Fitting Reaction**; and **Organic Chemistry**.

WURTZITE. A mineral zinc sulfide [CAS: 1314-98-3], (Zn, Fe)S, similar to sphalerite. Crystallizes in the hexagonal system. Hardness, 3.5–4; specific gravity, 3.98; color, brownish-black with resinous luster. Named after Adolphe Würtz, France.

X

XALSTOCITE. A pink to rose-pink variety of grossular garnet. Sometimes also called landerite or rosolite.

XANTHAN GUM. [CAS: 11138-66-2]. A very high-molecular-weight polysaccharide produced by pure culture fermentation of glucose by *Xanthamonas campestris*. The substance is readily soluble in hot or cold water, imparting a high viscosity at low concentrations. The solutions are pseudoplastic, with viscosity decreasing rapidly as shear rate increases. Heat, acid, and salt have little effect on the stability of its solutions. The substance is compatible with most other hydrocolloids, including starch. Xanthan gum undergoes a unique gel reaction with locust bean gum to produce a synergistic increase in viscosity. The gum is used as a thickening, suspending, emulsifying, and stabilizing agent in foods and has a number of important nonfood uses as well.

The primary structure of xanthan has been determined by chemical degradation and methylation analysis; it is composed of repeating units consisting of a main chain of D-glucopyranosyl residues with trisaccharide side chains made up of D-mannopyranosyl and D-glucopyranosyluronic acid residues.

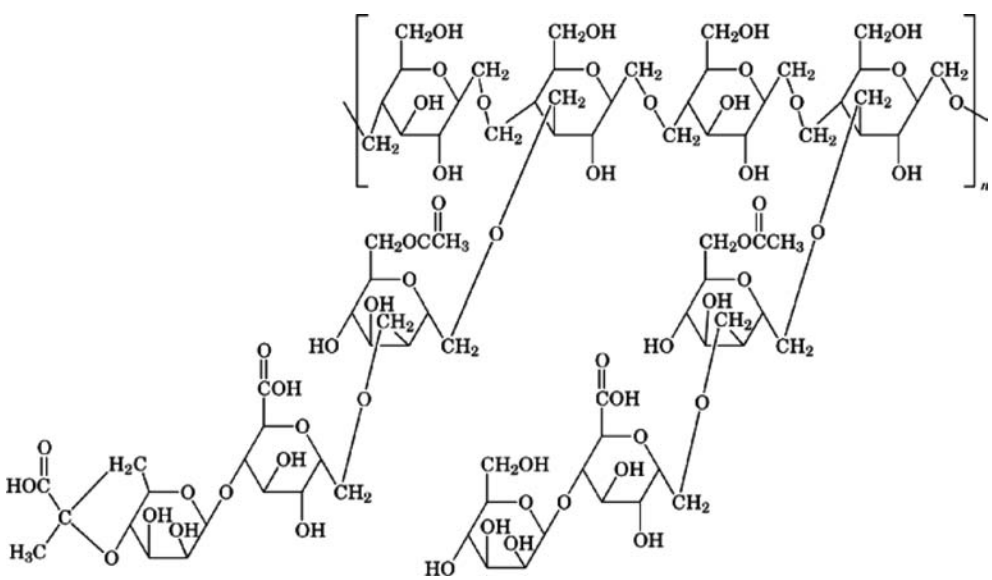
Approximately half of the terminal D-mannosyl residues have pyruvate present as 4,6-*O*-(1-carboxyethylidene) substituents. The pyruvate content has been shown to vary with culture conditions and strains of *X. campestris*. The internal D-mannosyl residue is acetylated at the O-6 position.

Xanthan gum has several desirable physical properties that explain the wide application range developed for this polysaccharide. The viscosity of xanthan gum solutions is highly pseudoplastic. Relatively low concentrations of the biopolymer produce highly viscous solutions that maintain viscosity over wide ranges of temperature and pH. Mono- and divalent cations enhance the stability of solution viscosity to exposure to elevated temperatures. The addition of salt to solutions of xanthan results in essentially stable solution viscosity from pH 1.5 to 13; salt also increases the yield value, ie, suspending power, of xanthan gum solutions. There is a surprisingly small effect on viscosity over a relatively large range of salt concentrations even though xanthan gum is a polyelectrolyte. At a polysaccharide concentration of approximately 0.35%, there is essentially no change in solution viscosity between 0.01 and 1% KCl. At concentrations of polysaccharide lower than 0.35%, the presence of salt slightly lowers the viscosity, whereas at concentrations higher than 0.35% gum, the presence of salt results in a slight increase in viscosity.

Using a variety of measurement techniques, a relatively wide range of molecular weights have been reported for xanthan gum preparations ($\sim 2 - 50 \times 10^6$). Two preparations of native xanthan gum have molecular weights of 13 and 50×10^6, as determined by light scattering measurements. By measuring the contour length of the molecule from electron micrographs, an estimate of 20×10^6 has been made. Sedimentation studies have yielded an average value of 7.6×10^6 and a range of values of $4 - 12 \times 10^6$. Using size-exclusion chromatography, average molecular weights of 1.8 and 2.4×10^6 have been measured. Low angle laser light scattering has given molecular weight estimations in the range of $4.1 - 12.2 \times 10^6$.

Structure and Conformation

The conformation of the biopolymer in solution has been a subject of debate. Several analytical methods have shown that the polymer goes through a phase transition at elevated temperatures, which depends on the concentration of salt. Increasing the temperature at low salt concentrations brings about a conformational shift from an ordered state to a disordered, random coil conformation. The change is associated with a decrease in solution viscosity and can also be characterized by changes in optical rotation and circular dicroism, nuclear magnetic resonance, and electron microscopy. The transition temperature increases with increasing sodium or calcium ion concentration, as well as with the acetate content of the polysaccharide, and decreases with increasing pyruvate content. The transition temperature is apparently independent of polymer concentration; this has been interpreted as evidence that the polymer is a single-stranded helix, and this conclusion has been supported by spectroscopic analysis of the polymer in solution. The crystalline structure of xanthan gum has been examined by X-ray diffraction and reported to be a single-stranded helix with a diameter of 2 nm, but the possibility that the molecule could form a double-stranded helix has not been ruled out. Evidence that the



native structure of xanthan is a double-stranded helix has been provided by light-scattering experiments.

The structure of xanthan has also been investigated by electron microscopy. A series of micrographs of native and denatured xanthan preparations show stiff, relatively straight rod-shaped structures, ranging from 2 to 10 μm long and 4 nm in diameter. Xanthan gum prepared using several methods shows sections of single- and double-stranded structures within a single polymer strand; apparently the polymer becomes partly unwound under the particular conditions used to prepare the sample for analysis. The method of preparation and treatment of the sample is important in determining what structural features will be present in the polymer, and treatments exist to change the polymer from one conformation to another. The effect of salt on single- and double-stranded structures has been studied, and a model for salt-induced extension and dissociation of native xanthan gum involving a two-step mechanism proposed. Lowering the salt concentration results in an extended double-stranded polymer; at even lower salt concentrations, dissociation of the double helix into single strands occurs.

Production and Utilization

The nutritional requirements of *X. campestris* have been studied in order to optimize the production of xanthan gum. Fermentations for the industrial production of xanthan gum are done at 28 °C, and utilize glucose concentrations from 1–5%. Higher glucose concentrations do not result in higher levels of gum biosynthesis. Saccharides such as sucrose, starch, and maltodextrins can also be used for gum production. The use of a completely defined media for gum production has been described. It has also been shown that some organic acids including pyruvic, succinic, and α-ketoglutaric acids increase the production of xanthan gum. It is necessary to maintain a neutral pH during fermentation in order to obtain maximal yields; during polymer biosynthesis the medium becomes acidic, but can be neutralized by the addition of a suitable base.

A typical commercial production process starts with an innoculum of *X. campestris*, prepared in a yeast extract containing broth, which is added to the production medium consisting of 3% D-glucose, 0.5% potassium phosphate buffer, 0.4% dried distillers solubles, and 0.01% magnesium sulfate. The stirred, aerated culture is held at 28 °C (32.4 °F) and after 96 hours approximately 50% of the glucose is converted into polymer. The medium is highly viscous, and water is added to reduce the viscosity to improve the removal of cells. The fermentation broth is heated to nearly 100 °C (212 °F) to pasteurize the liquid, and after cooling the polysaccharide is precipitated with ethanol or 2-propanol. The process of heating also causes the strands of polysaccharide to separate, and slow cooling allows the strands to reanneal between helices and form networks, improving the viscosity. The recovery of polymer is enhanced if potassium chloride is added to the mixture. The alcohol is removed and the material dried and packaged. Food-grade xanthan is tested during production and packaging to ensure that the material is not contaminated by microorganisms. It has been estimated that the average yearly production of xanthan gum for food markets is $18 - 22 \times 10^6$ kg ($8 - 10 \times 10^6$ lbs), with a value of $\$44 - 60 \times 10^6$.

The unusual rheological properties of xanthan gum have led to its use in a wide variety of food and industrial applications. It is frequently the thickener of choice because of its ability to maintain solution viscosity (for emulsion stabilization) in salts and acids, such as are found in salad dressings. It has been used extensively in no oil or low oil salad dressing formulations, and has been shown to provide long-term emulsion stability. U.S. FDA Standards of Identity also permit its use in sauces, puddings, bakery and pie fillings, and dry mixes for beverages. Xanthan gum can be mixed with carrageenan and galactomannans such as locust bean gum to improve gelling and stabilization of frozen dairy products and desserts. The synergistic interactions of xanthan gum and the galactomannans can be used in situations where fast gelling time is desirable or to reduce costs of additives.

Large quantities of xanthan gum are used by the oil and natural gas industry in several aspects of hydrocarbon production. See also **Hydrocarbons**; **Natural Gas**; and **Petroleum**. The high viscosity achievable at low concentration and the high suspending power efficiently remove bit cuttings while reducing friction substantially throughout the drill string. Xanthan is compatible with many additives frequently used to prepare drilling fluids, and drilling fluids can be made up of fresh, brackish, or salt water and still maintain viscosity. It can effectively thicken hydraulic fracture fluids that are employed to improve porosity in subterranean formations, where viscosity is required to suspend a propping additive such as sand which is then pumped underground into newly formed fissures. The excellent heat stability and salt compatibility frequently result in its selection over lower cost viscosifiers. Xanthan is also added to solutions pumped underground that are used to displace oil toward a collection well. It improves the sweeping efficiency of these flooding fluids enough to make them cost effective.

Other industrial uses for xanthan gum include thickening textile and carpet printing pastes, suspending pigments in ceramic glazes to improve glaze dispersion, and ink and clay coating formulations in the printing and paper industries, respectively. Agrochemical producers blend herbicides and insecticides with xanthan in order to improve application to plants. See also **Herbicides**; and **Insecticide**.

For references see the list in the entry on **Colloid Systems**. Other gums and mucilages are described in the entry on **Gums and Mucilages**.

XANTHOPHYLLS. See **Carotenoids**.

X-BAND. A frequency band used in radar extending approximately from 5.2 to 10.9 kilomegacycles per second.

X-CHROMOSOME. The human X-chromosome is one of the sex chromosomes. Females have two X-chromosomes in each cell, whereas males have an X- and a Y-chromosome. The X-chromosome is of average size and is gene poor, but is associated with a disproportionate burden of genetic diseases. The reason for this is that the majority of X-chromosome genes are present in a single copy in males, which permits the manifestation of recessive X-linked conditions. This creates the most familiar pattern of X-linked inheritance, first noted over two centuries ago for hemophilia and color blindness, in which males are affected and there is no male-to-male transmission. A further consequence of the male hemizygosity of X-linked genes is that inactivation of one of the X-chromosomes in females is needed in order to ensure the equivalence of dosage of X-linked gene products between males and females. X-inactivation has phenotypic consequences for carrier females of some X-linked conditions and for viability in cases of sex chromosome aneuploidies.

On March 17, 2005, an international team led by the Wellcome Trust Sanger Institute, Cambridge, UK publishes in Nature the most complete analysis of this remarkable chromosome. Other major contributions to the sequence came from groups at Baylor College of Medicine, Houston TX, USA, Institute for Molecular Biotechnology, Jena, Germany, Washington University Genome Sequencing Center, St Louis, MO, USA and Max-Planck-Institute for Molecular Genetics, Berlin, Germany.

Sex Chromosome Evolution

An explanation for the unique properties of the X-chromosome demands an understanding of mammalian sex chromosome evolution. Mammals have an XX/XY sex determining system, in which the Y-chromosome bears the critical male determining locus. It is widely believed that the sex chromosomes evolved from a pair of autosomes that were recruited to the sex determining process. A barrier arose against recombination between X and Y in the region of the sex determining locus and spread along the chromosomes. This was accompanied by the degradation of the affected segment of the Y-chromosome, which was never found in the homozygous condition and so was insufficiently maintained by selection. This hypothesis is invoked to account for the observation that the sex chromosomes are physically and genetically very different. The Y-chromosome now carries few functional genes with X-chromosome counterparts. Therefore, males are hemizygous for X-linked genes and so are affected by recessive X-linked conditions. See also **Y-Chromosome**.

X-Chromosome Inactivation

A dosage compensation system has evolved to ensure that the levels of gene products from the two X-chromosomes in females are equivalent to the levels from the single X-chromosome in males. The mechanism was proposed in 1961 by Mary Lyon and others and was based on the inactivation of one of the X-chromosomes in female cells early

in embryogenesis. In marsupials, the paternal X-chromosome is always inactivated (imprinted inactivation), whereas in the embryonic tissues of placental mammals either of the X-chromosomes can be inactivated. In the latter case, all descendants of the cell that inactivated the maternal or paternal X carry the same inactive chromosome. Therefore, female placental mammals are mosaic for the expression of X-linked genes for which they are heterozygous. The inactive X-chromosome (Xi) has several characteristics that distinguish it from the active one (Xa). The Xi is converted to a heterochromatic form (the *Barr* body, named for Murray Barr who first noted this in neurons from female cats), replicates late during the cell cycle, methylates its CpG islands, and is associated with hypoacetylated histone H4. These features are all consistent with transcriptional silencing.

The molecular basis of X-inactivation remains to be completely elucidated, though much is known of the details. The control of X-inactivation lies in the X-inactivation center (XIC), which is at Xq13 in humans. This region contains elements involved in X-chromosome "counting," choice of which chromosome to maintain in the active state (Xa), and in the initiation and propagation of inactivation on the other chromosome (Xi). A critical element of the XIC is the *Xist* gene, which encodes a 17-kb untranslated transcript. Before inactivation, *Xist* is expressed from both X-chromosomes. Once the choice of Xa is made, the *Xist* transcript from Xi is stabilized and begins to coat the Xi in *cis*, probably as part of a ribonucleoprotein complex. This coating eventually spreads along the full length of Xi.

The phenomenon of X-inactivation has a number of medically important consequences. Female carriers of X-linked recessive conditions can exhibit a mild disease phenotype owing to the inactivation of the normal X. In some cases, there is a skewing away from random inactivation, by selection against cells that inactivate the normal X [e.g., in X-linked agammaglobulinemia (XLA)]. Another consequence of X-inactivation is that X-chromosome aneuploid conditions, such as Turner syndrome (XO) and Klinefelter's syndrome (XXY), are phenotypically mild. That there is any clinical phenotype at all might be because of the existence of genes that escape inactivation on the inactive X-chromosome. Some of these genes lie in a pseudo-autosomal 2.5-Mb region (PAR1) shared between the tips of the short arms of the X- and Y-chromosomes, and maintained by an obligatory recombination in male meiosis. Others are found outside PAR1, and only a few of these have functional counterparts on the Y chromosome. The majority of these genes are found on the short arm of the X chromosome.

X-Chromosome and Disease

More than 300 diseases have been linked to genes on the X-chromosome, most of which have a recessive inheritance pattern. The genome sequence has been used in the isolation of more than 40 genes that are involved in medical conditions, including cleft palate and blindness. Hemizygous males inheriting a recessive genetic disorder are normally severely affected, whereas heterozygous females are often asymptomatic or have a more variable and milder clinical progression. Diagnostic features of X-linked recessive inheritance (Fig. 1) are:

1. There is no male-to-male transmission.
2. The majority of affected individuals are male.
3. All daughters of affected males are obligate carriers.
4. Sons of carrier females have a 50% chance of inheriting the X-chromosome carrying the mutant allele and so being affected. For the same reason, daughters of carrier females have a 50% risk of themselves being carriers.
5. Unaffected males cannot transmit the phenotype.

Only a few genetic disorders are classified as X-linked dominant. Examples include vitamin D resistant rickets, ornithine transcarbamylase deficiency (OTC), incontinentia pigmenti, and Rett syndrome. Hemizygous males are clinically more severely and uniformly affected, whereas the expression in heterozygous females is usually less clinically severe and more variable, presumably on account of the inactivation of the mutated X-chromosome in a proportion of cells. Characteristic features of X-linked dominant inheritance are (Fig. 2):

1. Male-to-male transmission does not occur.
2. All of the daughters of an affected male will be affected.

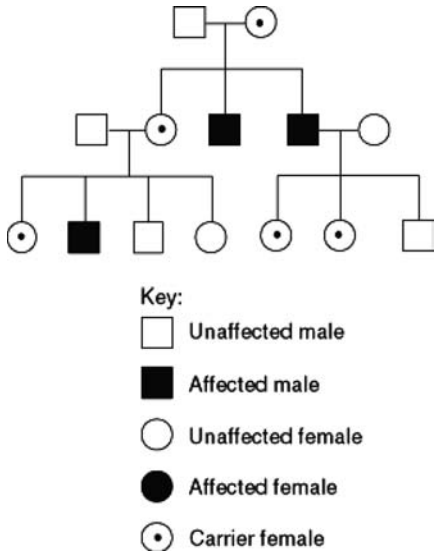


Fig. 1. Sample pedigree displaying features of an X-linked recessive inheritance pattern.

3. Offspring of affected females have a 50% risk of being affected regardless of sex.

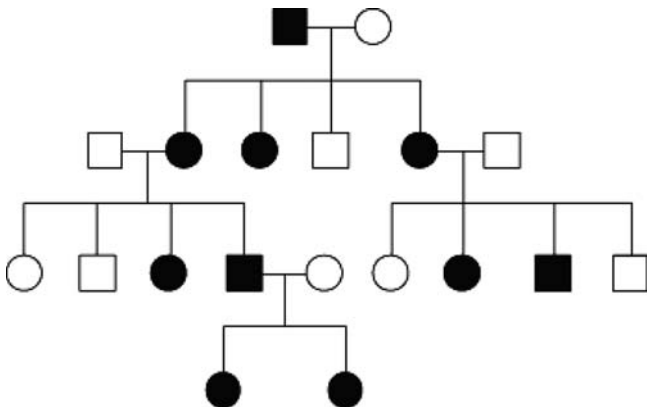

Fig. 2. Sample pedigree displaying features of an X-linked dominant inheritance pattern.

Descriptions of some X-linked diseases follow, but are limited to particular examples of importance historically and medically. See Fig. 3. For the most complete description of diseases, (see Online Mendelian Inheritance in Man:http://www3.ncbi.nlm.nih.gov/Omim/)

Duchenne muscular dystrophy (DMD) is estimated to affect one in 3,000 live male births. The disease usually presents between the ages of two and five with signs of muscular weakness in a "waddling" gait. Progressive muscular weakness results in confinement to a wheelchair between the ages of seven and twelve. Death usually occurs early in the second decade as a result of either severe respiratory insufficiency or acute myocardial insufficiency. Becker muscular dystrophy (BMD) shares many features with DMD but has a much milder progression. Diagnosis is generally in the second decade but patients are often mobile well into adulthood. The incidence is approximately one-third that of DMD but the longer life expectancy results in an approximately equal prevalence of the two diseases. See also **Muscular Dystrophy**.

DMD and BMD result from mutations in the dystrophin gene. The gene spans 2.4 Mb in Xp21.1 and is the largest known human gene. Dystrophin is a long rodlike molecule that links actin fibers in the cortex of muscle cells to the extracellular basal lamina by forming a bridge between actin and the dystrophin-associated sarcoglycan complex in the sarcolemma sheath surrounding the muscle fibers. A large proportion of dystrophin mutations are partial gene deletions or duplications of varying sizes (60% and 6–10%, respectively). Deletions that maintain the reading frame in the deleted

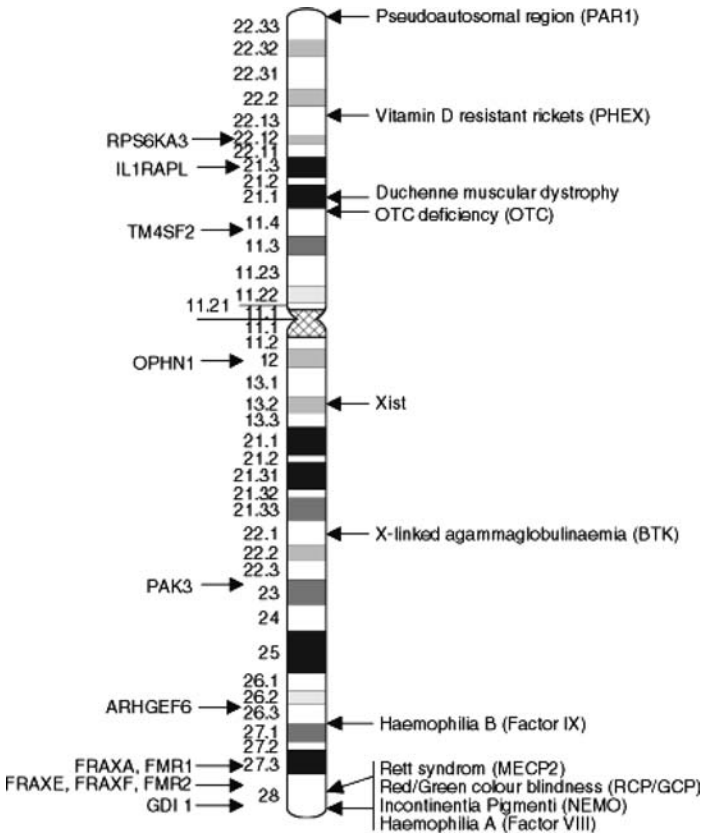

Fig. 3. Ideogram of the human X-chromosome showing the positions of the eight known non-specific mental retardation genes and the FMR1 gene (left), and genes for other selected X-linked conditions (right). The positions of the PAR1 region and the XIST gene are also shown.

transcript generally cause BMD, whereas those in which a frameshift has occurred usually cause DMD.

The blood clotting disorders hemophilia A and hemophilia B (Christmas disease) result from defects in the genes encoding factor VIII (Xq28) and factor IX (Xq27.1-q27.3), respectively. In both conditions the severity of the phenotype is variable but is characterized by the inability to form clots, resulting in spontaneous internal bleeding into the joints and muscles, and prolonged bleeding from wounds. Hemophilia A has an incidence of approximately one in 5,000 males and is famous for its transmission through the royal families of Europe via descendants of Queen Victoria. Almost half of the severe cases of hemophilia A (20% of all cases) are due to inversions caused by intrachromosomal homologous recombination between a repeat sequence in intron 22 of the factor *VIII* gene and two extragenic copies of the repeat sequence. Hemophilia B has an incidence of one in 30,000 male births. Hemophilia B is caused by a variety of missense mutations with few deletions or gross rearrangements indicating the protein is highly constrained. See also **Hemophilia**.

Mental retardation (MR) is one of the most common clinical disorders, with 2 to 3% of the population having learning difficulties and an intelligence quotient (IQ) less than 70. X-linked forms of MR (XLMR) can be classified as nonspecific (MRX), where the only clinical manifestation is MR, or as syndromic, where other distinguishing features are present.

Nonspecific X-linked mental retardation represents approximately 5% of all MR corresponding to a prevalence of 1 in 600 males in the general population. The identification of large families with XLMR has resulted in the mapping of 75 overlapping genetic intervals for MRX along the chromosome. These can be grouped into 12 to 15 nonoverlapping regions suggesting the involvement of a minimum of 10 to 12 genes. Eight *MRX* genes have been identified, all of which, despite encoding diverse and heterogeneous proteins, are directly or indirectly involved in signaling pathways.

Fragile X-syndrome is the most common form of inherited cognitive impairment after Down's syndrome. It is characterized by moderate to severe learning difficulties, macroorchidism, large ears, and a prominent jaw. The syndrome is caused by expansion of a CGG-triplet repeat in the 5¢untranslated region of the *FMR-1* gene located at Xq27.3. Normally this repeat is present in 5 to 50 copies, which are stably transmitted from generation to generation. In fragile X-syndrome the repeat length increases to 200 to 1,000 copies, inducing methylation of the promoter region of the *FMR-1* gene thus preventing transcription and production of its product, FMRP. The expansion also results in a fragile site (a nonstaining gap visible in a metaphase chromosome spread) in the chromosome, designated FRAXA. See also **Down's Syndrome**.

Rett syndrome is a progressive neurological developmental disorder with an incidence of one in 20,000. The disorder is inherited in an X-linked dominant fashion, and is lethal in hemizygous males before birth. Female patients with Rett syndrome develop normally until the age of 6 to 18 months when they suffer developmental arrest, then regression, seizures, and develop stereotypic "hand-washing" movements. Rett syndrome is caused by a defect in the gene encoding methyl-CpG-binding protein-2 (MECP2) in Xq28.

Several genes associated with color blindness are located at Xq28, including those encoding red and green color pigments. About 8% of males in Western Europe are color blind. Of these, 75% are green color blind, and 25% are red color blind. The genes encoding the light sensitive pigments required for color vision are part of a gene family and are very similar structurally, probably arising by gene duplication from a common ancestral pigment gene. A single red pigment gene and a variable number of green pigment genes are arranged in a tandem array in Xq28. See also **Color Blindness**.

Klinefelter syndrome is caused by the presence of one or more extra copies of the X chromosome in a male's cells. Extra genetic material from the X chromosome interferes with male sexual development, preventing the testicles from functioning normally and reducing the levels of testosterone.

Typically, males with Klinefelter syndrome have one extra copy of the X chromosome in each cell, for a total of two X chromosomes and one Y chromosome (47,XXY). Less commonly, affected males may have two or three extra X chromosomes (48,XXXY or 49,XXXXY) or extra copies of both the X and Y chromosomes (48,XXYY) in each cell. The extra genetic material may lead to mental retardation and other medical problems.

Klinefelter syndrome can also result from an extra X chromosome in only some of the body's cells. These cases are called mosaic 46,XY/47,XXY.

Triple X syndrome (also called 47,XXX or trisomy X) results from an extra copy of the X chromosome in each of a female's cells. Females with trisomy X have three X chromosomes, for a total of 47 chromosomes per cell. It remains uncertain why an extra copy of the X chromosome is associated with tall stature and learning problems in some girls and women.

Females with more than one extra copy of the X chromosome (48,XXXX or 49,XXXXX) have been identified, but these conditions are rare. The extra genetic material may lead to mental retardation and other medical problems.

Turner syndrome results when each of a female's cells has one normal X chromosome and the other sex chromosome is missing or altered. The missing genetic material affects development and causes the characteristic features of the condition, including short stature and inability to conceive a child (infertility).

About half of individuals with Turner syndrome have monosomy X (45,X), which means each cell in an individual's body has only one copy of the X chromosome instead of the usual two sex chromosomes. Turner syndrome can also occur if one of the sex chromosomes is partially missing or rearranged rather than completely missing.

Some people with Turner syndrome have a chromosomal change in only some of their cells. Some cells have the usual two sex chromosomes (either two X chromosomes or one X chromosome and one Y chromosome), and other cells have only one copy of the X chromosome. These cases are called Turner syndrome mosaics (45,X/46,XX or 45,X/46,XY).

XENIA. That phenomenon, in which two plants, having been crossed, the characters of the male parent appear at once in the seed. Ordinarily the characters of neither parent are recognizable so early. Xenia is particularly well shown in corn plants, in which there is a conspicuous endosperm, the outermost layer of which is the aleurone layer. This endosperm results from the fusion of a sperm nucleus with two polar nuclei in the process of fertilization. The endosperm therefore is triploid. In corn it is frequently distinctly colored, with yellow dominating over white. It is possible therefore to pollinate a white-grained corn with a yellow parent, all the grains resulting from the cross being yellow since the gene which produces the yellow color is in every cell of the triploid endosperm. Red or purple colors often occur in corn, usually in the aleurone layer, and are dominant over colorless aleurone, so again crosses may be made showing directly the effect of genes from the male parent on the endosperm of the seed.

In some plants the influence of the male element is more extensive, involving tissues which are of female origin. This phenomenon is known as metaxenia. See also **Plant Breeding**.

XENOBLAST. A term proposed by Becke in 1903 for metamorphic crystals with undeveloped crystal faces.

XENOCRYST. A term proposed by Sollas in 1894 for crystals, usually corroded, which are foreign to the magma from which the igneous rock in which they occur has crystallized.

XENOLITH. A fragment, large or small, of a foreign rock included in an igneous mass. The term is derived from the Greek, meaning stranger and stone. Xenoliths, both large and small, are best displayed at the contacts or margins of batholiths.

XENOMORPHIC. The texture or fabric of an igneous rock having or characterized by crystals not bounded by their own crystal faces and which have their form impressed upon them by preexisting adjacent mineral crystals.

XENON. [CAS: 7440-63-3]. Chemical element, symbol Xe, at. no. 54, at. wt. 131.30, periodic table group 18 (inert or noble gases), mp. $-112\,^{\circ}C$ ($-170\,^{\circ}F$), bp $-107.1 \pm 2.5\,^{\circ}C$ ($-160.8 \pm 36.6\,^{\circ}F$), density 3.5 g/cm^3 (liquid at $-109\,^{\circ}C$ ($164\,^{\circ}F$)). Specific gravity compared with air is 4.561. Xenon (Greek *xenon* meaning "stranger") was discovered by Morris Travers and William Ramsay in 1898 in the residue left over from evaporating components of liquid air. Solid xenon has a face-centered cubic crystal structure. At standard conditions, xenon is a colorless, odorless gas and does not form stable compounds with any other element. Due to its low valence forces, xenon does not form diatomic molecules, except in discharge tubes. It does form compounds under highly favorable conditions, as excitation in discharge tubes, or pressure in the presence of a powerful dipole. Xenon forms a hydrate much more readily than argon, at a pressure slightly above 1 atmosphere pressure at $0\,^{\circ}C$ ($32\,^{\circ}F$). The element also forms additional compounds with a number of organic substances, such as $Xe{\cdot}2C_6H_5OH$ with phenol, which has a dissociation pressure of 1 atmosphere at $4\,^{\circ}C$ ($39.2\,^{\circ}F$). See also **Chemical Elements**.

In 1962, the compound xenon platinum hexafluoride was synthesized by Bartlett. Later in the same year, Classen confirmed the synthesis and prepared the first binary compound of an inert gas, xenon tetrafluoride [CAS: 13709-61-0], a stable crystalline compound, mp about $90\,^{\circ}C$ ($194\,^{\circ}F$). The compound was prepared by heating a 5:1 mixture of fluorine and xenon to $400\,^{\circ}C$ ($752\,^{\circ}F$), then cooling it rapidly to room temperature. Since the original research, additional xylene-fluroine compounds have been reported, including XeF_2, XeF_4, XeF_6, XeF_6, $XeSiF_6$, XeO_2F_2, and Na_4XeO_6, as well as the hydrate. By heating xenon and fluorine above 10 atmospheres (up to 170 atmospheres), at $250\,^{\circ}C$, Weinstock, Weaver, and Krop obtained XeF_5 and XeF_6 in an equilibrium mixture. D.F. Smith, S.M. Williamson, and C.W. Koch have reported the preparation of XeO_3 from the hexafluoride and tetrafluoride. XeO_3 is a white, crystalline, explosive compound.

Xenon also forms compounds, possibly clathrates, with certain substances in nonstoichiometric proportions. Crystalline compounds with benzene or hydroquinone, formed under 40 atmospheres pressure, contain about 26% xenon by weight. Alkaline hydrolysis of XeF_6 produces salts of octavalent xenon. No persistent divalent or tetravalent compounds are found in aqueous solution, but the former is intermediate in hydrolysis of the fluorides, and the latter in reactions of XeO_3 with XeF_2, H_2O_2, and various organics.

Xenon occurs in the atmosphere to the extent of approximately 0.00087%, making it the least abundant of the rare of noble gases in the atmosphere. In terms of abundance, xenon does not appear on lists of elements in the earth's crust because it does not exist in stable compounds under normal conditions. However, xenon because of its limited solubility in H_2O, is found in seawater to the extent of approximately 950 pounds per cubic mile (103 kilograms per cubic kilometer). Commercial xenon is derived from air by liquefaction and fractional distillation. There are nine natural isotopes ^{124}Xe, ^{126}Xe, ^{128}Xe, through ^{132}Xe, ^{134}Xe, and ^{136}Xe, and seven radioactive isotopes ^{123}Xe, ^{125}Xe, ^{127}Xe, ^{133}Xe, ^{135}Xe, ^{137}Xe and ^{138}Xe, all with relatively short half-lives, the longest ^{127}Xe with a half-life of about 36 days. See also **Radioactivity**. First ionization potential, 12.127 eV; second, 21.1 eV; third, 32.0 eV. Van der Waals radius 2.20 Å Electronic configuration $1s^22s^22p^63s^23p^63d^{10}4s^24p^64d^{10}5s^25p^6$.

Xenon is one of the elements of interstellar matter that is found in some meteorites. As reported by Lewis and Anders 1983, at least three types of xenon are present in carbonaceous chondrites. Two are abundant but controversial; the third is rare, but easy to explain. In 1964, Reynolds and Turner (University of California at Berkeley) examined the C2 chondrite Renazzo and were seeking xenon 129 (from radioactive decay of iodine 129). A controlled, step-heating process was used. In addition to finding xenon-129, the investigators found that in the fractions released between 600 and $1100\,^{\circ}C$ (1112 and $2012\,^{\circ}F$), the heavy isotopes of Xe ranging in mass from 131 through 136 were present. They found that these isotopes were enriched by as much as 6% with respect to primordial xenon. This enrichment increased from isotope 131 to isotope 136, as it does in the xenon formed by the fission of uranium and other heavy elements. Reynolds and Turner thus suggested that the new xenon component came from the fission of some extinct heavy element that had once been present in the meteorite. It was also noted that xenon 124 and 126 were also enriched in the meteorite, but in as much as these isotopes do not form by fission, their enrichment was not fully explained. The two sets of xenon components have been named H (heavy) and L (light) and, although apparently of different origins, they have proved inseparable in meteorites. See also **Meteoroids and Meteorites**.

Xenon also has been detected in some of the planetary atmospheres, such as that of Mars. Check various entries on planets in this book.

The gas finds principal application in special electronic devices and lamps. Xenon, in a vacuum tube, produces a beautiful blue glow when excited by an electrical discharge. Xenon lamps have been developed which provide a constant light (described as sunlight-plus-north-sky light) even when there are significant voltage changes. Thus, the lamps do not require voltage regulators. For a given wattage, xenon lamps have been found to deliver a greater light output. For example, an 800-watt xenon lamp will produce 2,000 lumens as compared with a 1,000-watt incandescent lamp that produces only about 200 lumens. Xenon also has found application in certain lasers. It has been found that xenon produces mild anesthesia, but cannot be used for surgery because the quantity required would

cause asphyxiation. Xenon is used in bubble chambers, probes, and other applications where its high molecular weight is of advantage in the atomic energy field. Potentially, xenon is of interest as a gas for ion engines. The perxenates have been used as oxidizing agents in analytical chemistry. Xenon 133 and 135 are produced by neutron irradiation in air-cooled nuclear reactors. Xenon 133 has been found useful as a radioisotope in various studies.

Health and Safety. The gas can be safely kept in normal sealed glass containers at standard temperature and pressure. Xenon is non-toxic, but many of its compounds are toxic due to their strong oxidative properties.

Because xenon is heavier than air, the speed of sound in xenon is slower than that in air, and when inhaled, lowers the resonant frequencies of the vocal tract. This produces a characteristic lowered voice pitch, analogous to the high-pitched voice caused by inhalation of helium. For several reasons, the inhalation of xenon is more dangerous than the inhalation of helium. First, xenon has poorly understood anaesthetic effects, similar to those of nitrous oxide. Inhalation can cause mild-to-moderate, short-lasting effects, including a pounding sensation associated with light and sound.

Because of the dangers associated with xenon inhalation, many universities no longer allow the practice as a general chemistry demonstration. Xenon is in any case quite expensive. The gas sulfur hexafluoride is generally used as a replacement.

XENOPSYLLA CHEOPSIS. The species of Indian rat flea which is found in tropical regions. The flea is parasitic to humans and other animals and transmits bubonic plague and tapeworms.

XENOTOPIC. The fabric of a crystalline sedimentary rock in which the majority of the constituent crystals are anhedral. Fabric found in evaporites, chemically deposited cement, and recrystallized limestone or dolomite.

XEROPHYTES. These are plants that are adapted to grow in regions in which there is a decided lack of water, as in deserts. Plants growing in such localities have become modified in various ways that enable them to survive. Since the greatest problem is the lack of water, xerophytes must be formed as to avoid excessive loss of water. There are several factors that reduce water loss. In many of these plants the leaves are greatly reduced in size or are completely lost, as in most Cacti and many Euphorbias. Most of the water lost to the plant passes through the stomata of the leaves and stem epidermis. In many xerophytes the stomata are sunk deep in small pits. The number of stomata is often reduced and also their size. As a further protection against loss of water the epidermis may be covered with a very thick cuticle.

The sap of xerophytic plants has properties which make it hold water tenaciously, tending to reduce loss. Many xerophytes have a fleshy habit, so that greater space is available for storage of water. Sometimes the root is tremendously swollen, in others the stem becomes the enlarged part, while in many it is the leaves. Often the leaves form dense tufts which cause great reduction of free surfaces.

Xerophytes are extremely tolerant of prolonged drought. Some may be kept free from water for several years, yet revive and grow when supplied with water. Most of these plants cannot stand too much water, quickly rotting under such conditions. Many species of xerophytes are covered with thorns. This is commonly assumed to protect them against grazing animals.

Many xerophytes have extensive shallow root systems, which spread through a wide area, to take advantage of the occasional rains in the desert habitats. Others obtain water by sending roots very deeply into the soil. Creosote bushes, for example, may have roots several hundred feet (in excess of 120 meters) long.

XEROSIS. Abnormal dryness of the skin.

XEROSTOMIA. Insufficient flow or production of saliva, causing dry mouth.

XI PARTICLE. A hyperson with a rest-mass energy of about 1318.4 MeV, an isospin quantum number $\frac{1}{2}$, an angular momentum spin quantum number $\frac{1}{2}$, and a strangeness quantum number 2. Symbol, Ξ.

XIPHOSURA. The horseshoe or king crabs, a class of the phylum *Arthropoda* containing only a single genus, *Limulus*, with five species, one found along the Atlantic coast of North America from Florida to Nova Scotia and the other four on the eastern coast of Asia. See accompanying figure. They are animals of ancient lineage, showing no important change from fossils of the Triassic.

King crabs are distinguished by the following characters: (1) The cephalothorax is covered by a continuous arched plate of horseshoe shape. (2) Six segments of the abdomen are fused to form a continuous piece, hinged to the cephalothorax. (3) The abdomen bears a long caudal spine, the telson. (4) The appendages of the cephalothorax include six pairs associated with the mouth, five of them chelate. The five posterior pairs have the basal segments formed for crushing food. (5) The appendages of the abdomen are six pairs of broad plates bearing gills and used in swimming. (6) There are two large compound eyes and two smaller median eyes.

These animals burrow in sand and mud near the shore, feeding on small animals. They come to shore to deposit their eggs in sand. They are of little economic importance but have been used as food for pigs and domestic fowls, and to a limited extent as fertilizer. (See Fig. 1)

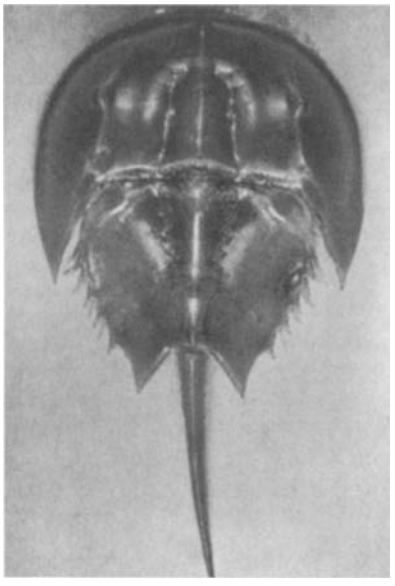

Fig. 1. Xiphosura, King or horseshoe crab. (*A.M. Winchester.*)

XMM-NEWTON (The High-Throughput X-Ray Spectroscopy Mission). XMM-Newton is the European Space Agency's (ESA) second X-ray observatory. It was launched by an Ariane V rocket from Kourou,

French Guiana on December 10, 1999, into an eccentric orbit with a perigee of 7000 km, an apogee of 107000 km and an inclination of $-40°$. This orbit allows long uninterrupted observations of up to 42 hours duration. With a projected lifetime of 10 years, XMM-Newton is allowing astronomers to conduct sensitive X-ray spectroscopic observations of a wide variety of cosmic sources. The first XMM-Newton announcement of opportunity (AO-1) attracted the attention of an astonishing ~2000 professional astronomers worldwide, which amounts to approximately 25% of the world's astronomical community. The amount of proposals received was seven times higher than could be accommodated. XMM-Newton is the largest scientific satellite ever built in Europe with a mass of nearly 4 tons and a length of nearly 10 m (32.8 feet). See Fig. 1. Mission operations are conducted from the European Space Operations Center (ESOC) in Darmstadt, (Germany) and Science Operations from ESA's Vilspa tracking station in Villafranca (Spain). Ground stations in Kourou (French Guyana) and Perth (Australia) are used to provide almost continuous contact with XMM-Newton.

The limiting sensitivity for spectroscopic investigations with XMM-Newton is around 10^{-15} erg cm^{-2} s^{-1} and sources as faint as a few times 10^{-16} erg cm^{-2} s^{-1} can be detected. XMM-Newton uses grazing incidence Wolter I optics with a focal length of 7.5 m ($24\frac{1}{2}$ feet) to provide an effective aperture of 4500 cm^2 at 1 keV (12.4 Å) and 1000 cm^2 at 10 keV (1.24 Å). Each telescope module consists of 58 closely packed mirror shells with a maximum diameter of 70 cm ($27\frac{1}{2}$ inches) and a length of 60 cm ($23\frac{1}{2}$ inches). The angular resolution across the full energy range is 15 arc seconds half energy width, and the X-ray field of view is ~30 arc minutes. A coaligned Optical Monitor (OM) provides simultaneous coverage of the wavelength range 1600–6000 Å. As well as broad band spectroscopy between 0.1 and 15 keV (0.8–120 Å) using the European Photon Imaging Counter (EPIC), a Reflection Grating Spectrometer (RGS) allows medium resolution spectroscopy with resolving powers between 100 and 700 over the wavelength band 5–35 Å (350–2500 eV).

EPIC consists of X-ray imaging cameras located behind each of the three telescope modules of XMM-Newton. The detectors are cooled CCD devices (2 MOS-CCD cameras, 1 pn-CCD camera), operating in a photon-counting mode to provide simultaneous imaging and nondispersive spectroscopy (spectral resolving power ~7 at 0.2 keV to ~70 at 15 keV) for every field that XMM-Newton observes. See Fig. 2.

The mission's aim of providing a medium-resolution spectroscopic capability is achieved by means of the two RGS. The grating arrays are placed directly behind two of the three mirror modules, in front of the EPIC MOS cameras, and each intercepts ~50% of the converging beams. A position and energy sensitive readout at the spectroscopic (secondary) focus is performed by strip arrays of nine MOS CCDs for each RGS. The energy resolution of these CCDs is used to separate the overlapping diffraction orders -1 and -2 and to reject background arising from diffuse X-rays as well as from particle radiation or internal detector effects.

The OM enables XMM-Newton to provide simultaneous coverage of the telescope field in the optical and ultraviolet wavebands The 30 cm Cassegrain telescope covers a 17 by 17 arcminute field with an angular resolution of ~1 arc second through the use of a photon-counting detectors. This instrument is also equipped with a standard set of U, B and V filters as well as specific UV wavelength band filters and 2 grisms for low-resolution dispersive spectroscopy over the full wavelength band.

The first science data from XMM-Newton fully demonstrate the capabilities of the spacecraft's telescopes and science instruments. The spacecraft viewed three regions of the sky: part of the Large Magellanic Cloud, the Hickson Cluster Group 16 and the star HR 1099. Results from these observations were officially presented at a press conference in 2000 February. These targets were chosen because they all present a variety of X-ray extended and point sources and are scientifically very interesting regions. XMM-Newton is now routinely making the observations proposed by the scientists involved in the development of the instruments and ground segment.

X-NETWORK WINDOW. By way of software, a portion of a cathode-ray tube (CRT) can be singled out for detailed viewing upon command of the viewer. In this scheme, one or more windows can be designated as "dedicated" for use on an X-network, making it possible for several stations along the network to obtain instant information that may be of interest to several operators, as in a manufacturing or processing network.

X-RAY. In 1895, W. Roentgen of Würzburg, Germany discovered x-rays accidentally while experimenting with a Crookes tube. Roentgen observed the fluorescence of a barium platinocyanide screen that happened to lie

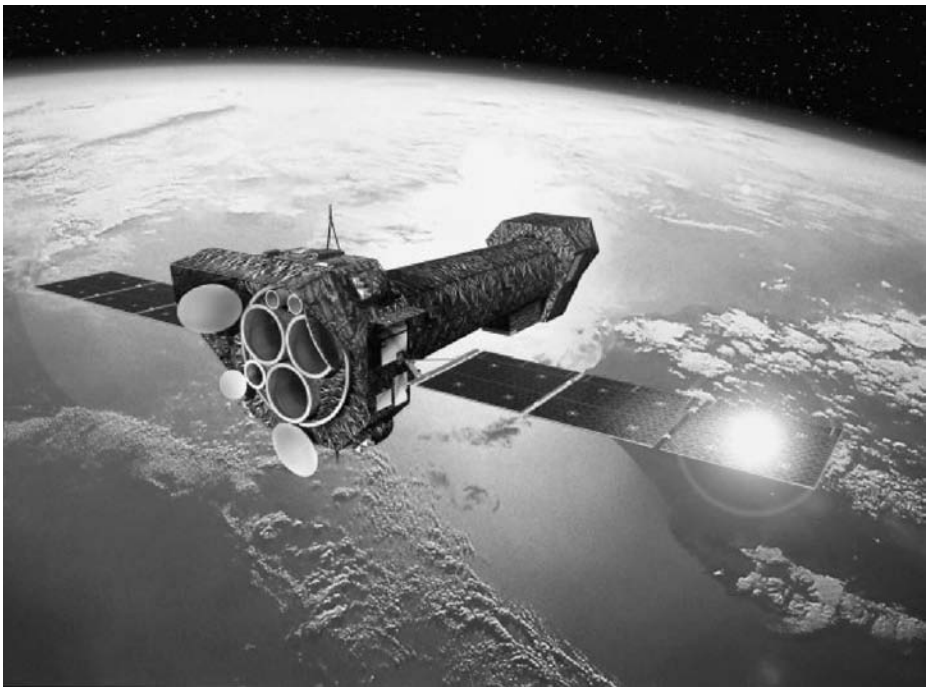

Fig. 1. Artist's impression of XMM-Newton (*ESA/Ducros*).

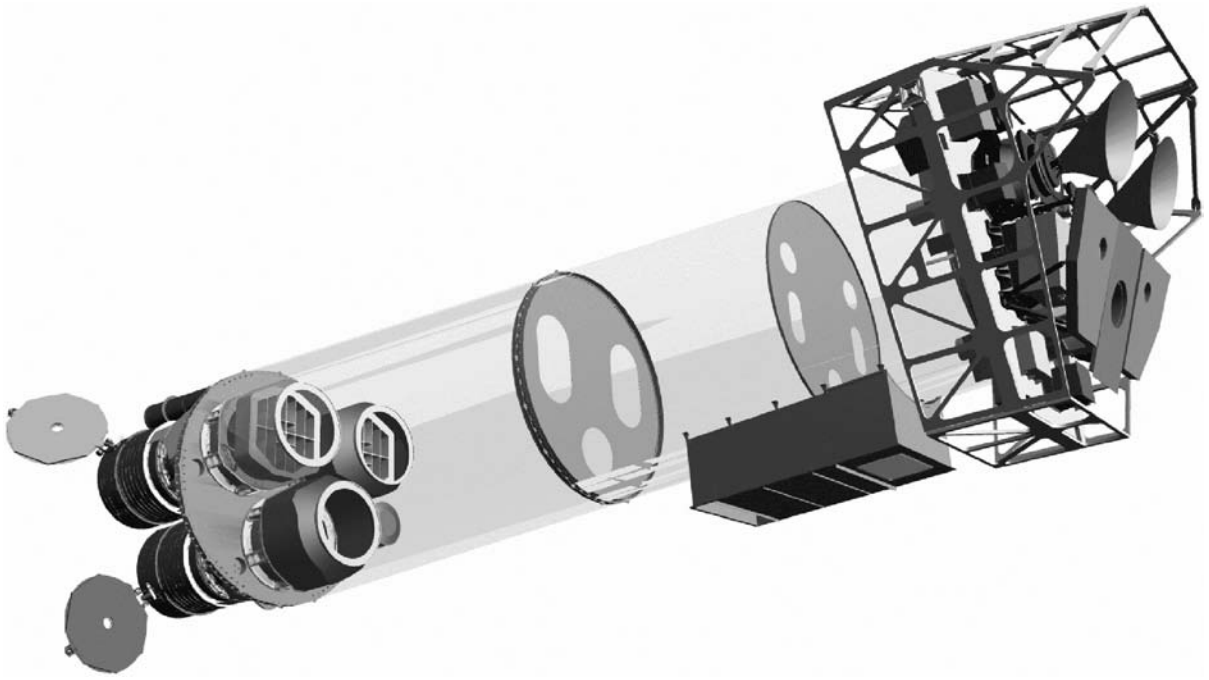

Fig. 2. If the XMM spacecraft were made of glass, one could gain a view of its payload. The X-ray telescopes, two with Reflection Grating Arrays, are visible at the lower left. At the right end of the assembly, the focal instruments are shown: The EPIC MOS cameras with their radiators (black/green "horns"), the radiator of the EPIC p-n camera (violet) and those of the (light blue) RGS receivers (in orange). The black box at the bottom of the bus is the outgassing device. (*Dornier Satellitensysteme GmbH*.)

near the tube and traced the effect to something that emanated from the spot where the cathode rays struck the tube wall. Putting the tube in a pasteboard box made no difference; so it was not light or ultraviolet radiation that caused the fluorescence. Investigation rapidly followed and relatively soon, x-rays were being used by surgeons to examine the bones of living people. X-ray photos are also used in industry. See Fig. 1.

It was soon found that x-rays arise wherever cathode rays encounter solids; that "targets" of high atomic weight yield more copious X-rays; and that the greater the speed of the cathode particles, the more penetrating, or the "harder" the X-rays are. Special tubes were designed for producing x-rays. The earlier tubes were of the Crookes type, depending on the conduction of ionized gas. Those most used now are thermionic, of the Coolidge type, with a hot-wire cathode operating in a high vacuum; a construction which permits the passage of very high-speed electrons under voltage control, the quantity of them, and the intensity of the resulting X-rays, being regulated by the filament temperature. See also **Roentgen, Wilhelm Conrad (1845-1923)**.

Early experiments indicated that x-rays are something essentially different from light, an erroneous conclusion based upon the failure to observe regular reflection, refraction, or diffraction. We now know that this failure was due to the extremely short wavelength of the rays, the range of which extends from the extreme ultraviolet into the gamma-ray region, that is, from 10^{-7} to 10^{-9} centimeter. It is also known that X-rays are produced: (1) when electrons, accelerated in a vacuum, strike a target and lose kinetic energy in passing through the strong electric fields surrounding the target nuclei, thus giving rise to bremsstrahlung and resulting in a continuous x-ray spectrum; and (2) by the transitions of atoms from higher energy states to K, L, ... energy states, thus giving rise to characteristic x-rays. The term x-rays is not used to refer to the characteristic radiation from an element of atomic number Z less than 10, since the wavelengths of such radiation exceed those in the x-ray range. However, every element has its characteristic X-ray spectrum, when used as a target, although according to the Duane and Hunt law the radiation also depends on the accelerating voltage.

There are three principal means of detecting x-rays: the fluorescent effect, the photographic effect, and the ionizing effect. The only method at first available for distinguishing radiation of different wavelengths was to measure their penetration or their absorption coefficient in various substances. The discovery of the X-ray diffraction or grating effect of crystals, by von Laue, Friedrich, and Knipping, in 1912, made it possible to analyze the rays and measure their wavelengths very much as light is studied with the spectroscope. When X-rays of given wavelength are incident upon a crystal turned in various directions, the layers of atoms, at certain angles

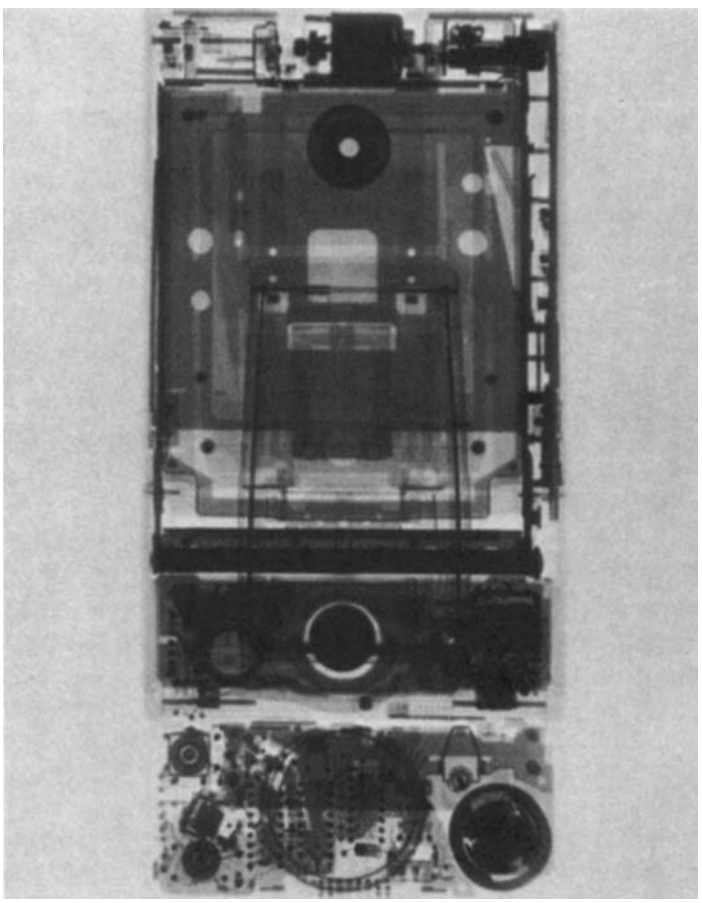

Fig. 1. Industrial-type x-ray photo of a Polaroid camera.

of incidence, reflect wave trains in phase with each other which, if caught on a photographic plate, produce a "Laue pattern." While the matter is not as simple as in the case of light incident on a diffraction grating, it is nevertheless possible to interpret such patterns in somewhat the same way as a line spectrum, and to deduce the wavelength from it. A unit convenient for expressing X-ray wavelengths is the "X-unit," which is 10^{-11} centimeter or 0.001 angstrom. See also list of references at the end of X-Ray Analysis.

X-RAY ANALYSIS. X-rays occupy that portion of the electromagnetic spectrum between 0.01 and 100 angstroms (Å). Their range of approximate quantum energy is from 2×10^{-6} to 2×10^{-10} erg, or from 106 to 100 eV. Important X-ray analytical methods are based upon: (1) fluorescence; (2) emission; (3) absorption; and (4) diffraction. These methods are used qualitatively and quantitatively to determine the element content of complex mixtures and to determine exactly the atomic arrangement and spacings of crystalline materials. See also **Ion Microprobe Mass Analyzer**.

Source of X-rays. X-rays are emitted by atoms that are bombarded with energetic electrons. This results from two separate effects: (1) deceleration of high-speed electrons as they pass through matter, and (2) ionization of individual atoms which abruptly stop the electrons. The first effect results in a continuous-type spectrum; the second effect results in characteristic line spectra.

Continuous Spectrum. The bulk of X-radiation arising from electron bombardment is the continuous spectrum. If an individual electron is abruptly decelerated, but not necessarily stopped, in passing through or near the electric field of a target atom, the electron will lose some energy DE, which appears as an X-ray photon of frequency $v = \Delta E / h$, where h is Planck's constant. An electron may experience several such decelerations before it is finally stopped, emitting x-ray photons of widely different energy and wavelength. A few electrons will be stopped in a single process, losing their entire energy and emitting an X-ray photon having the exact energy of the incident electron.

X-Ray Spectral Lines. These result when the incident electrons knock orbital electrons out of an atom. If an ejected electron is from one of the inner orbits of the atom (Fig. 1), an electron from an outer shell will fall to the inner orbit to fill the vacancy. The decrease in potential energy of this electron in approaching the nucleus results in the emission of an X-ray photon having an energy exactly equal to that lost by the electron. The wavelength λ for such photons is related to ΔE by $\lambda = tch/\Delta E$, where c is the velocity of electromagnetic energy and h is Planck's constant. Because the energy of orbital electrons is quantized, the X-ray photons can have only certain definite wavelengths which are characteristic of the atom. This situation is somewhat analogous to the more familiar ultraviolet and visible-emission spectra of materials, the difference being that the optical spectra are the result of electron transitions between energy levels of just the outermost electrons of the atoms.

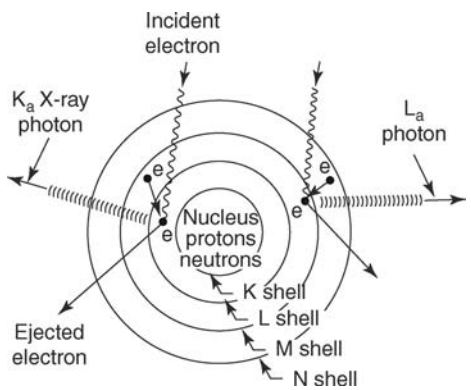

Fig. 1. Origin of X-ray spectra due to electron bombardment.

X-rays resulting from an electron transition filling an electron vacancy in the innermost shell of an atom are known as K x-rays or K lines; those from the L shell are known as L lines, and so on.

Generation of X-rays. An important component in an X-ray analytical device is an x-radiation generator. A high-vacuum Coolidge type tube, wherein electrons are emitted from a heated tungsten filament and accelerated by a high voltage to an anode (target) is a common source of x-rays. See Fig. 2.

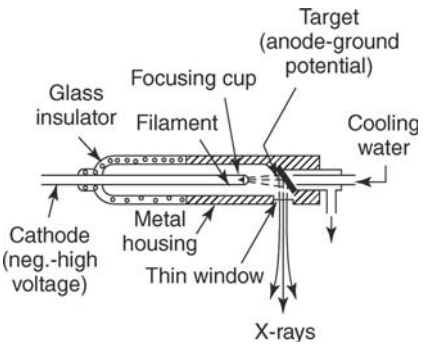

Fig. 2. High-voltage, high-vacuum X-ray tube.

A wide variety of tubes is available. All high-power (high-current) commercial tubes employ a water-cooled anode. Tubes of this type have been built with ratings up to 10 kilowatts.

Detection of X-rays. Detectors include (1) Geiger-Mueller tube, (2) ionization chambers, (3) scintillation counters, (4) proportional counter, (5) electron-multiplier tubes, and (6) nondispersive detectors using cooled lithium-drifted Si detectors. See Fig. 3.

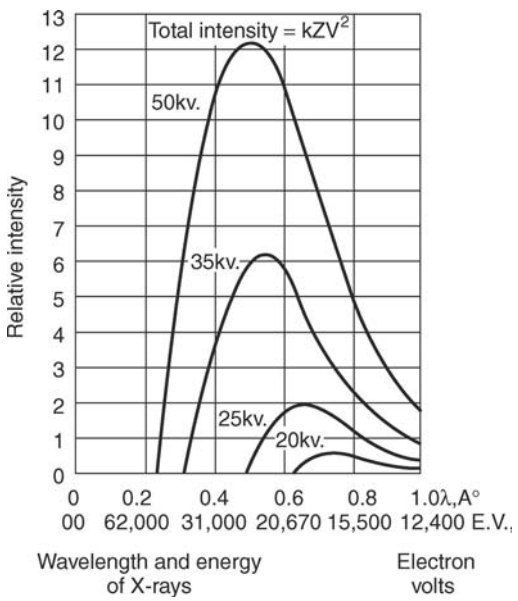

Fig. 3. Continuous X-ray spectrum of tungsten ($Z = 74$) at various tube voltages.

X-ray Crystallography. X-rays penetrating below the surface of crystalline materials are scattered by the individual parallel layers of atoms; each atomic layer acts as a new, although weak, source of X-rays. To be reinforced in a given direction at an angle θ (Fig. 4), the spacing d between crystal planes must be rigorously related to the wavelength of the radiation. At a given angle, X-rays of one definite wavelength will be constructively reinforced. These variables are related by Bragg's law.

$$n\lambda = 2d\sin\theta$$

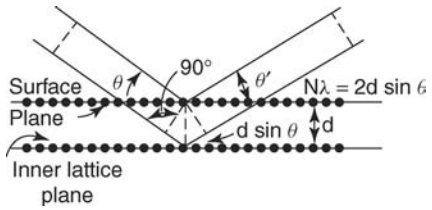

Fig. 4. Reflection of X-rays from internal crystal plane.

where n is an integer. Note that θ is measured relative to the crystal face rather than to the perpendicular.

In addition to fulfilling this wavelength requirement, the energy will be diffracted only at an angle equal to the angle of the incident x-rays, independent of wavelength; otherwise, destructive interference is possible, and the "reflected" energy is negligible.

X-Ray Analyzer, Electron-Microprobe. Advantages of this analytical instrument include: (1) analysis can be confined to very small (microsamples) amounts of materials; (2) the particular material to be analyzed need not be physically separated from its surrounding materials, as is often required with many analytical methods; and (3) through the development of associated instrumentation, diagnostic techniques, and information displays, the method can be quite fast. Limits of detection in solid solution are from approximately 0.005 to 0.5%, depending upon the elements and sample matrixes involved. See Fig. 5. Concentrations as low as 10^{-16} gram may be measured.

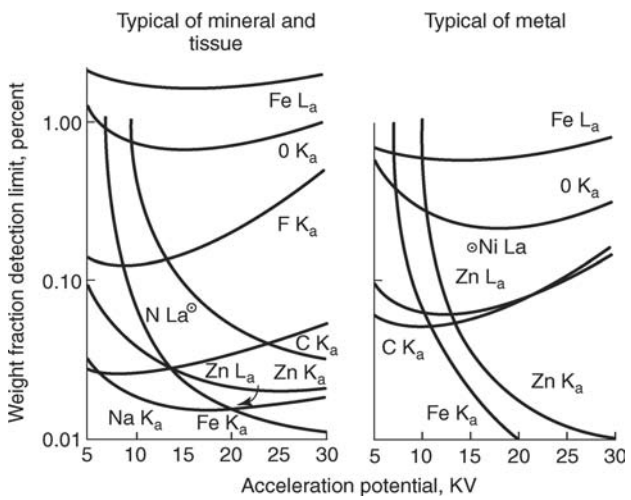

Fig. 5. Typical weight-fraction detecting limits of electron microprobe X-ray analyzer.

Mainly used for metallurgical studies, nonmetallics also may be analyzed when samples are properly prepared. Biological applications include tooth and bone samples, cytochemical problems and staining techniques, physiochemical problems, and studies in pathology. Relative weight-fraction-detection limits for most elements in biological specimens are in the general range of 0.01 to 0.10%. Electronics industry applications include studies of diffusion phenomena, electrical-contact surfaces, interfaces on transistors, and microcircuitry analysis.

As shown by Fig. 6, electrons from an electron gun are directed to the sample through an electron optical system. Once the electron beam strikes the sample, a number of signal sources are activated, including (1) high-energy backscattered electrons, (2) low-energy secondary electrons, (3) cathodoluminescence, and (4) x-rays. Some heat also is generated within the sample. Volume d_3 of the specimen is that *volume from which X-rays are emitted*.

The X-rays produced may be detected nondispersively by a proportional counter whose output may be separated as a function of energy by a pulse-height analysis system into the various wavelength components. Better detection sensitivities, however, can be obtained through the use of a fully focusing diffracting-crystal spectrometer in conjunction with a proportional

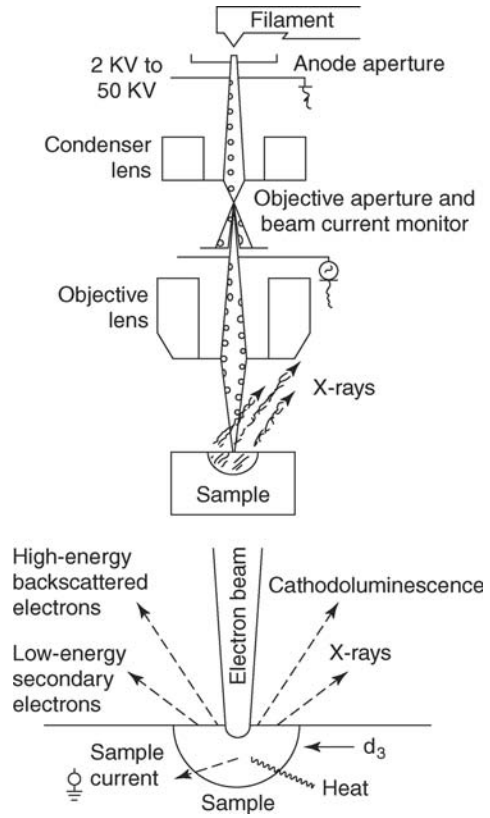

Fig. 6. Electron gun and probe-forming lens system of an integrated electron probe.

detector and the necessary pulse-height analyzer. As shown by Fig. 7, the necessary condition for fully focusing optics is to have the x-ray source, the crystal, and the detector slit all placed on a common circle. This geometry requires that the diffracting-crystal planes be bent to the diameter of the Rowland circle.

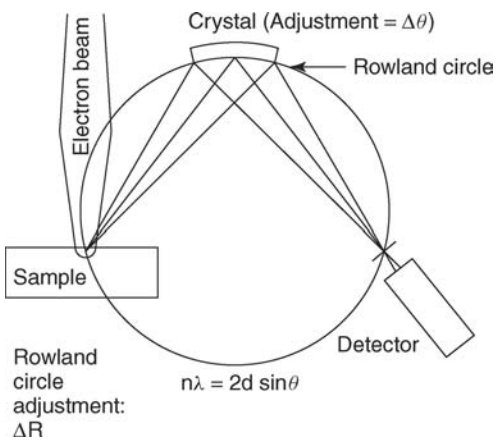

Fig. 7. Geometry of a fully focusing diffracting-crystal spectrometer.

Spherical aberration at the detector slit is minimized by further grinding the crystal surface to fit the radius of the Rowland circle. With the resultant Johansson optics, the crystal radius is fixed, and the 2θ range of the spectrometer is scanned by moving the crystal radially away from the source and, at the same time, rotating it into the detector to achieve a true focus throughout the spectrometer range. X-rays particularly of a wavelength greater than 2Å, and electrons are highly absorbed in an air atmosphere. Thus, the spectrometer must be enclosed in a vacuum of the order of 10^{-5} torr. The present wavelength range of interest extends from approximately 1 to 100Å. Diffracting crystals to cover this range must provide broad wavelength coverage, high diffraction efficiencies for

high peak-count intensities, good resolution, and good resulting peak-to-background ratios. Crystals that meet these objectives include lithium fluoride, ammonium dihydrogen phosphate (ADP), ethylenediamine *d*-tartrate. (EDT), quartz, and sodium chloride.

Detectors. Of the three commonly used X-ray detectors — (1) Geiger counter, (2) scintillation counter, and (3) proportional counter — the latter is used most frequently for electron-probe microanalysis. In the wavelengths from 1 to 10Å, sealed proportional counters may be used. For longer-wavelength analysis — in the range from 10 to 93Å — the thinnest possible detector window is required to limit spectral attenuation. Nitrocellulose windows have proved successful. Nondispersive detection systems using cooled Li-drifted Si are also applicable.

An *optical microscope* is required in the system to provide the analyst with a means of reference to identify various sample areas for analysis. Sample stages may hold single or multiple samples and are provided with means for moving the sample in x, y, and z planes without breaking the system vacuum. After the point of interest is located on the specimen, the data may be read out in a number of ways: (1) quantitative and seimquantitative information may be obtained by processing the x-ray detector signal through a rate meter to a strip-chart or X–Y recorder; (2) scaler systems also provide direct readout of quantitative data integration; and (3) for operational convenience, a data translator and typewriter or teletype printout system may be connected directly to record digital-counter information as hard copy.

X-ray Fluorescence Analysis. One of several types of spectrochemical techniques now used for laboratory analysis. The method is nondestructive. The characteristic X-ray spectrum of each element bears a simple direct relationship to the atomic number. The relation of the wavelength λ to the atomic number Z is

$$\frac{1}{\lambda} a Z^2 \text{(Mosley's law)}$$

Since the X-ray spectral lines come from the inner electrons of the atoms, the lines are not related to the chemical properties of the elements or to the compounds in which they may reside. Because the characteristics of the X-ray spectra are associated with energies released through transitions of electrons within the inner shells of the atom, the spectra are simple. Most practical X-ray fluorescence analysis involves the detection of radiation release through electron transitions from outer shells to the K shell (K spectra), outer shells to the L shell (L spectra) and, in very few cases, from outer shells to the M shell (M spectra).

The simplest form of energy source available for commercial instrumentation is that obtained from an X-ray tube. For samples containing predominantly low-atomic-number elements, as in cement raw mix, the most efficient excitation is accomplished by using an X-ray tube target material of relatively low atomic number, such as chromium. Elements having higher atomic numbers are most effectively excited by high-atomic-number targets, such as tungsten or platinum. An optimum target material is rhodium for the analysis of a broad range of elements. The X-ray tube irradiates the sample, which in turn emits characteristic fluorescent radiation of its atoms.

Once X-ray fluorescence is produced from the sample by means of an X-ray tube, appropriate components of the instrument (Fig. 8) separate this radiation into its characteristic wavelengths, detect the energy emitted from each excited atom, and produce a signal that is representative of the number of atoms (concentration) of the elements in the sample. Typical excitation conditions (x-ray tube) are 50 kilovolts, 35 milliamperes. Bragg's law of X-ray diffraction is satisfied by the condition $N\lambda = 2d\sin q$, where λ is the wavelength and θ is the angle of incidence and diffraction of X-rays from a crystal whose lattice spacing is defined by d and N, the order of harmonic of the diffraction. For almost all fluorescence analysis, $N = 1$. The usable x-ray spectrum normally extends from 0.1 to about 20Å. A helium or vacuum path is required for x-ray analysis of elements with atomic numbers lower than $Z \cong 24$ (wavelengths longer than 2.3Å).

Instrumentation can provide for simultaneous elemental analysis using fixed, preselected X-ray detection channels and scanners or a goniometer to provide one or more channels that can be tuned to a wide wavelength coverage. Up to 30 monochromator positions are possible. Typical crystal materials covering the practical wavelength range of 1 to 20Å are lithium fluoride, silicon oxide, sodium chloride, EDT, and ADP. Optimum

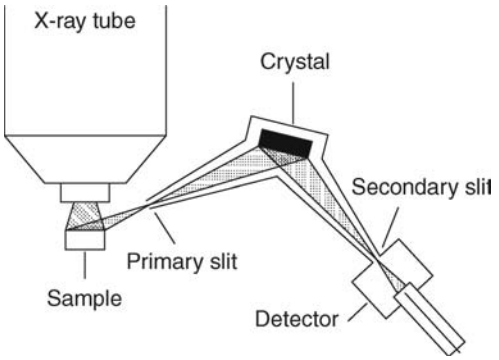

Fig. 8. Optical path for one monochromator used in an industrial X-ray fluorescence analyzer.

analytical data for the elements of interest are obtained by using fully focusing Johansson curved and ground crystals.

An optical diagram of a Johansson curved-crystal spectrometer is given in Fig. 9. Each spectrometer of an x-ray quantometer may be equipped with optimum crystal-detector combinations for specific determinations in a wide variety of matrixes, including steel, aluminum, copper-base materials, ores, cement, and slags — in both liquid and solid states.

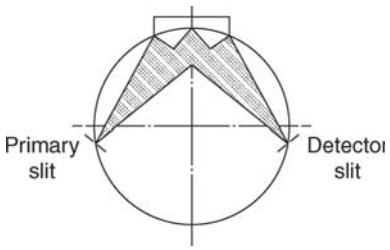

Fig. 9. Optical diagram of Johansson curved-crystal spectrometer.

The diffracted X-radiation is detected by Geiger, proportional, or semiproportional detectors. See Fig. 10. The detector of each monochromator generates pulses, which are a measure of the intensity of radiation of each wavelength. The pulses are filtered through a discriminator in order to avoid undesired interferences. Pulses shrinking due to an increase of frequency of pulses is automatically compensated. Collected pulses are transferred to a computer for processing and output. See Fig. 11.

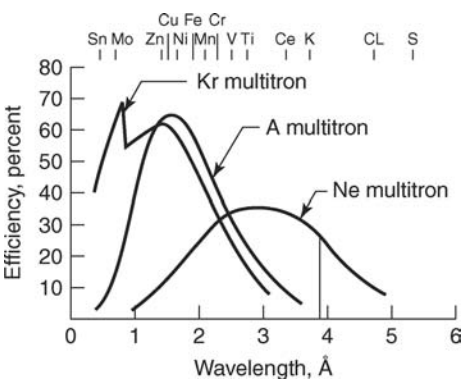

Fig. 10. Relative efficiency of X-radiation detectors.

The transition from laboratory to automated instrument to achieve high-speed continuous analysis of dry or wet materials primarily involves the sample-handling and presentation hardware.

Limits of detectability for the desired elemental analyses vary depending upon the matrix, elements, methods of sample preparation, and quality of instrumentation applied. Generally, these are on the order of 1 to 100 parts per million. The limit of detectability, however, is only one criterion

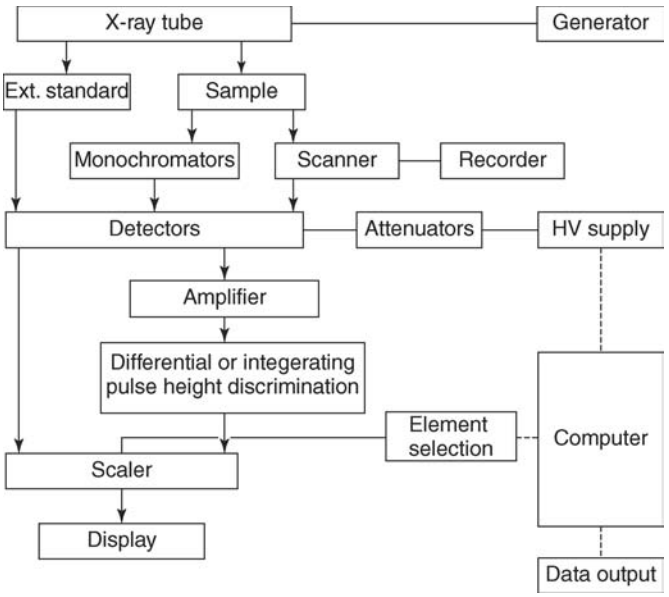

Fig. 11. System configuration of X-ray fluorescence analyzer.

in evaluating methods of analysis. The time of analysis is important, particularly in production and process control laboratories. In multi-element spectrometers, it is possible to perform as many as 30 simultaneous elemental determinations in from 20 to 120 seconds, depending upon the material being analyzed.

X-RAY ASTRONOMY. The X-rays detected by X-ray astronomers, like those put to use in industry, medicine and laboratory research, must be produced by high-energy particles. It is not surprising, then, that an X-ray image of the cosmos can look very different from an optical image.

X-ray images reveal hot spots in the universe — regions where particles have been energized or heated to temperatures of millions of degrees by strong magnetic fields, violent explosions, or intense gravitational fields. X-ray astronomy has shown that these extreme conditions exist in an astonishing variety of places, ranging from the bizarre warped space around black holes to the vast spaces between galaxies.

Because the Earth's atmosphere absorbs X-rays, X-ray observatories must be placed high above the Earth's surface. This means that the ultra-precise mirrors and detectors, together with the sophisticated electronics that conveys the information back to Earth must be able to withstand the rigors of a rocket launch, and operate in the hostile environment of space.

The first hint that cosmic X-rays exist came in 1949, when a team of scientists led by Herbert Friedman at the Naval Research Laboratory in Washington, DC used detectors aboard a rocket to detect X-rays coming from the sun. Solar X rays come from the hot outer layers of the sun's atmosphere called the corona.

Thirteen years later, in 1962, a team led by Riccardo Giacconi of American Science and Engineering (AS&E) in Cambridge, Mass. using a greatly improved detector, discovered X-rays coming from a source beyond the solar system in the constellation of Scorpius. This source was named Scorpius X-1. They also discovered that the X ray sky is never dark, but is illuminated with a smooth background glow.

In contrast to the sun, which radiates only one-millionth of its energy in X rays, Scorpius X-1 radiates over 99% of its energy as X rays. This showed that the AS&E team had discovered an entirely new type of object. Within a year these results were confirmed by the AS&E group and by the Naval Research Laboratory group. A new field of astronomy had been born.

By 1970 about thirty cosmic X-ray sources had been discovered. Some were associated with the remnants of supernova explosions, one was associated with a giant galaxy called M87, and another with 3C273, an extremely distant, energetic type of source called a quasar. Most of the sources were X-ray stars like Scorpius X-1, whose nature at this time was still unknown.

In the early 1970s, NASA's Uhuru X-ray satellite, equipped with a relatively simple instrument, a sensitive X-ray detector similar to a Geiger counter attached to a viewing pipe to locate the source, made some remarkable discoveries. Uhuru, which was built and operated by the AS&E team, detected over 400 X-ray sources. Uhuru's observations helped scientists solve the mystery of the X-ray stars. They showed that they were neutron stars or black holes pulling matter from nearby companion stars. As the matter falls onto the neutron star or black hole, it is heated to tens, even hundreds of millions of degrees and becomes a bright X-ray source. See also **Galaxy**.

A black hole does not have a surface in the normal sense of the word. See also **Black Hole**. It is more like a whirlpool in space with a critical range of influence. The critical distance from a black hole is called the event horizon. Anything that is pulled inside the event horizon, matter, visible light, X rays, is doomed. It cannot escape the black hole and must fall inward. X ray observations allow scientists to observe matter just a fraction of a second before it passes beyond the event horizon. Since the discoveries of Uhuru, one of the primary objectives of X-ray astronomy has been to learn more about these bizarre objects.

Uhuru also detected X rays from over a dozen supernova remnants, from a few galaxies and from gigantic systems containing thousands of galaxies. These discoveries emphasized the need for an X-ray telescope that could make images like an optical telescope.

This was a difficult undertaking, because X-rays do not reflect off mirrors the same way that visible light does. The energetic X-ray photons penetrate into the mirror and are absorbed. They reflect only if they strike the mirror at grazing angles, in much the same way that a pebble skips across a pond. X-ray mirrors must be precisely shaped and aligned nearly parallel to incoming X-rays. The mirrors look more like barrels than the familiar dish shape of optical telescopes.

NASA's Einstein Observatory, launched in 1978, was the first large X-ray telescope with mirrors capable of making images of sources outside the solar system. It imaged, shock waves from exploded stars, detected X-rays from normal stars, white dwarfs, neutron stars, black holes, galaxies, and clusters of galaxies containing over a thousand galaxies. In all, Einstein located accurately over 7,000 X-ray sources. The observations of the hot gas in galaxy clusters made possible a new way to study the mysterious dark matter that surrounds many galaxies. See also **Einstein Observatory (HEAO-2)**.

The Roentgensatellite or ROSAT, a joint venture between Germany, the United Kingdom, and the United States, carried an even larger X-ray telescope into orbit in 1990. It expanded the number of known X-ray sources to more than 60,000 and has proved to be especially valuable for investigating galaxy clusters and the coronas of stars. See also **ROSAT (Roentgen Satellite)**.

In the 1990s, several X-ray satellites were launched, culminating with NASA's Chandra X-ray Observatory and the European Space Agency's XMM-Newton, both in 1999.

In 1993, the Advanced Satellite for Cosmology and Astrophysics (ASCA) was launched. ASCA, was Japan's fourth cosmic X-ray astronomy

mission, and the second for which the United States is providing part of the scientific payload. ASCA was the first satellite to use a CCD X-ray camera in conjunction with its X-ray mirrors. This camera, which operates much like a camcorder or digital camera, allowed astronomers to make images with more information about the energy of the individual X-rays. ASCA operated successfully till July 15, 2000 when it was transferred into a safe-hold mode. The satellite re-entered on March 2, 2001 after seven and half years of scientific observations.

ASCA was followed by the Rossi X-ray Timing Explorer (RXTE), launched December 30, 1995. The RXTE was a special purpose NASA satellite that has the unique capability to study rapid time variability in the emission of cosmic X-ray sources over a wide band of X-ray energies, and has made valuable contributions to the understanding of neutron stars and black holes. See also **Rossi X-ray Timing Explorer (RXTE)**.

The BeppoSAX satellite is a major program of the Italian Space Agency with participation of the Netherlands Agency for Aereospace Programs. It was launched on April 30 1996 from Cape Canaveral and it is still operational. It is the first X-ray mission with a scientific payload covering more than three decades of energy from (0.1 to 300 keV) with a relatively large effective area, medium energy resolution and imaging capabilities in the range of 0.1–10 keV. BeppoSAX has proved to be especially useful for X-ray imaging the sources associated with gamma-ray bursts, and monitoring the X-ray afterglow of these puzzling sources. See also **BeppoSax (Satellite)**.

The XMM-Newton was launched from Kourou, French Guiana on December 10, 1999. XMM-Newton is a large Multi-Mirror X-ray astrophysics observatory developed by the European Space Agency (ESA) and the second cornerstone of the Horizon 2000 Science Programme. XMM-Newton carries three very advanced X-ray telescopes. They each contain 58 high-precision concentric mirrors, delicately nested to offer the largest collecting area possible to catch the elusive X-rays, and an optical monitor, the first flown on an X-ray observatory. This observatory will enable astronomers to conduct sensitive measurements of the X-ray spectrum of a wide variety of cosmic sources, and should be a powerful complement to the Chandra X-ray Observatory. See also **XMM-Newton (The High-Throughput X-Ray Spectroscopy Mission)**.

NASA's Chandra X-ray Observatory was launched by the Space Shuttle Columbia in July of 1999. It contains four sets of nested mirrors, which can produce images with 30 times more detail than any previous or existing X-ray telescope. It is the only X-ray telescope capable of producing X-ray images of the same quality as an optical telescope. The mirrors have been polished to a smoothness of a few atoms. If the surface of the state of Colorado were polished to same relative smoothness as Chandra's mirrors, Pike's Peak would be less than one inch tall!

Chandra's mirror assembly has four pairs of mirrors nested inside one another. The mirror surface is coated with iridium, a material more reflective than gold. Two sensitive, electronic X-ray cameras are used to collect the X rays focused by the mirrors. Scientists specify which camera will be at the focus for their observation. The High Resolution Camera uses an array of 69 million tiny glass tubes and a grid of electrically charged wires to determine the position and arrival time of each individual X ray and to reconstruct a high-resolution image of the celestial source of the X rays. The other camera is the Advanced CCD Imaging Spectrometer (ACIS) which works much like a camcorder or digital camera. It contains ten X-ray-sensitive CCD chips, each with over a million pixels, to record the position and energy, or color of the X rays. Even more detailed information about the energy of the incoming X rays can be obtained by inserting two screen-like instruments, called transmission gratings, into the path of the X rays. The gratings disperse the X rays into a high energy rainbow, containing thousands of distinct X-ray colors.

One of Chandra's early targets was the brilliant Orion star cluster, a cosmic birthing ground for stars. Stars in the Orion cluster were formed during the past few million years, so they are mere infants compared to our 4.5 billion year old sun. In one observation of the Trapezium region of the cluster, Chandra detected a thousand X-ray stars. Some are well known, massive, optically bright stars. Some are still embedded in the cloud of dust and gas from which they formed; they can be seen with an infrared, but not an optical telescope. A few are thought to be failed stars called brown dwarfs, because of their small mass.

Many young stars produce intense flares that make them a thousand times brighter in X rays than the sun. The cause of these flares is poorly understood, and scientists are hopeful that Chandra will help them to understand the bright, stormy youth of stars.

If the early stages of a star's development are wild, the end can be much more violent. When a massive star runs out of fuel, it undergoes a catastrophic explosion called a supernova. See also **Nova and Supernova**. The explosion, which is one of the most violent events in the universe, blows the star apart. The elements created by nuclear reactions inside the star over its lifetime — carbon, nitrogen, oxygen, and all the other elements heavier than helium — are spread into space.

The matter thrown off by the supernova creates a bubble of multimillion degree gas called a supernova remnant. This hot gas will expand and produce X-radiation for thousands of years. Chandra is the ideal instrument for studying these remnants. A team of scientists from MIT used Chandra to observe E0102-72, the remains of a star that exploded in a nearby galaxy. They found a ringlike structure that was thirty light years across and expanding at five million miles an hour. They determined that the ring was exceptionally rich in oxygen. It contained enough oxygen to mix with hydrogen and create more than a billion oceans. Thus confirmed the theory that massive stars provide most of the oxygen in the universe.

Chandra has also observed several giant black holes in the centers of galaxies, and come up with some surprises. The black hole in the center of the Milky Way galaxy, which has the mass of three million suns, is surprisingly weak in X rays, and the giant black hole in the center of the Andromeda Galaxy, which is surrounded by gas at an unexpectedly cool million degrees. See also **Andromeda**; and **Galaxy**. Current theories predict that the gas falling into the central black hole in Andromeda should be ten times or more hotter than is observed. Further Chandra observations of giant black holes should tell more about how a black hole swallows matter, and how space and time is warped by a black hole.

One of the most intriguing features of giant black holes is that they do not suck up all the matter that falls within their sphere of influence. Some of the matter falls into the black hole, and some explodes away from the black hole in high energy jets that move at near the speed of light.

Chandra has imaged a spectacular example of such a jet in Centaurus A, a nearby galaxy noted for its explosive activity. The image shows the nucleus, which is believed to harbor a giant black hole, and X-ray jets erupting from the center of the galaxy over a distance of 20,000 light years. The presence of bright X-ray jets means that electric fields are continually accelerating electrons to extremely high energies over enormous distances. Exactly how this happens is a major puzzle that Chandra may help to solve.

At the relatively nearby distance of eleven million light years from Earth, Centaurus A, has long been a favorite target of astronomers because it is the nearest example of a class of galaxies called active galaxies. Active galaxies are noted for their intense, bright cores and explosive activity, which are presumed to be due to a giant black hole in their center.

Active galaxies may be the solution to one of the oldest mysteries of X-ray astronomy, the X-ray background that was discovered in 1962. Many astronomers suspected that it was due to extremely distant active galaxies. They were unable to prove this, however, for no X-ray telescope until Chandra has had both the sharp vision and sensitivity to detect the individual sources.

Using Chandra, two teams of astronomers, from NASA's Goddard Space Flight Center, and Penn State University, have resolved over 70% of the background glow into individual sources, most of which are galaxies with a bright central core.

The nature of the remaining sources is not known. They could be galaxies so distant that the optical light gets absorbed by cool gas during its long journey across the universe. Or galaxies that are completely surrounded in dust. Or galaxies that have yet to form stars and are still just clouds of hot gas with a central giant black hole.

The giant clouds of hot gas in galaxy clusters pose another mystery. About 10% of all galaxies are part of huge clusters of hundreds or thousands of galaxies, X-ray observations show that the space between the galaxies is filled with a gas with temperatures in the range of 30 to 100 million degrees. There is enough gas in each galaxy cluster to make more than a hundred trillion stars.

The pressure of this hot gas is so great that it should have dispersed long ago. Since it has not, some additional force must be holding it together. The only known force that is strong enough is gravity. The galaxies cannot

provide the necessary gravity, nor can the hot gas. An unseen form of matter, called dark matter, must be holding the cluster together. The amount of dark matter needed is greater than the galaxies and gas put together. If this percentage hold true for all galaxies and clusters of galaxies, then most of the matter in the universe is in some dark form.

The dark matter is one of the greatest riddles of modern astronomy. What is it? Possibilities include dark planetlike objects, white dwarfs, and black holes. Most scientists believe that it is in the form of some as yet undiscovered subatomic particle, called a WIMP, for Weakly Interacting Massive Particle, that does not give off light in any form, and can be detected only through its gravity.

With observations from Chandra and other telescopes, astronomers should soon know how much dark matter the universe contains. However, it may be a long time before they know what it is, and how it has shaped our universe. See also **Chandra X-Ray Observatory**; and **X-Ray**.

X-RAY ENERGY LEVELS. See **Energy Level**.

X-RAY IMAGING, MEDICAL: TOMOGRAPHY AND RADIOGRAPHY. Medicine is largely devoted to preventing disease or injury, diagnosing what is wrong when disease or injury may be present, and treating the patient to alleviate pain and, when possible, to cure the problem. Diagnosis is often a major challenge, as the patient's symptoms are frequently relatively unspecific and might be caused by a variety of conditions. Meeting this challenge usually requires conducting various tests, including laboratory analyses and imaging procedures. These tests are all products of technological advances in the practice of medicine that have occurred in the 20th century. A century ago, physicians were severely limited in the tools available to help them arrive at a correct diagnosis. Most diagnoses were made from a verbal description of the patient's symptoms, combined with the patient's history and supplemented by use of the physician's senses to detect unusual odors, visual appearances, abnormal sounds, physical sensations, and, at times, an odd taste. Although significant problems may have been present within the patient's body, they frequently provided few external clues, and the physician was guided toward a diagnosis largely by his (or, in a few cases, her) intuition and experience. Needless to say, the final diagnosis was uncertain or incorrect in more than a few cases.

A major advance in the physician's ability to detect and diagnose disease and injury occurred in 1895 with the discovery of x rays by the physicist Wilhelm Roentgen in Würzburg, Germany. See also **X-Ray**. Today, x-ray imaging systems are used in hospitals, clinics, and physicians' offices worldwide for the detection and diagnosis of a wide spectrum of illnesses and injuries. In general, an x-ray imaging system consists of several components. An x-ray tube serves as the source of x rays that penetrate the patient and impinge on an image receptor such as a fluorescent screen or digital detector. The image is "captured" photographically or electronically and processed to accentuate anatomic features of interest in the patient. This image is interpreted by the physician to arrive at an opinion concerning the health status of the patient. The image may be stored physically or electronically for future referral.

Projection Radiography

Nature and Production of X-Rays. X rays are a form of electromagnetic radiation similar to infrared, visible, and ultraviolet light except higher in energy. They are widely used in medicine to produce images (radiographs) of virtually every region of the body. To achieve acceptable images, a source of x rays is required that

1. provides a sufficient number of x rays in a short interval of time,
2. allows the user to vary the x-ray energy,
3. produces x rays in a reproducible fashion, and
4. meets current standards of safety and operational efficiency.

The source almost universally employed for imaging is the x-ray tube. In this device x rays are released as high-speed electrons impinge on a target of a heavy metal such as tungsten.

The main components of a modern x-ray tube are shown in Fig. 1. As electrical current heats the tungsten filament in the cathode, electrons are boiled off (thermionic emission) and accelerated toward the target in the anode through a potential difference of from 20 000 to 150 000 V (20–150 kVp, where kVp denotes the peak kilovoltage across the tube). A focusing cup around the filament helps direct the electrons onto a small area (the focal spot) of an annular target that is embedded in a larger disk (the anode). X rays are released in all directions as the electrons interact in the target. The x rays are restricted by collimators outside the x-ray tube to confine the x-ray beam to the anatomic region of interest in the patient. Although intense bursts of x rays can be produced in this manner, most (>99%) of the electron energy is dissipated as heat in the target (Hendee and Ritenour, 1992). The anode rotates at several thousand revolutions per minute to spread the heat over a larger volume of target metal to keep the temperature of the metal from reaching its melting point.

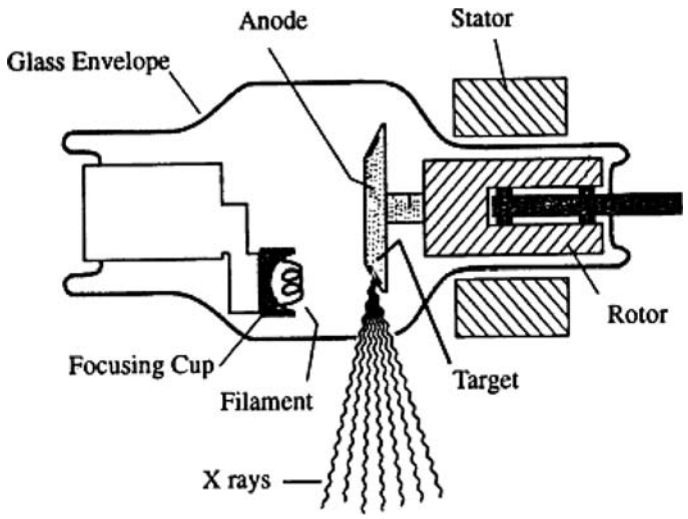

Fig. 1. Components of a modern diagnostic x-ray tube.

As the high-speed electrons penetrate the target metal, they interact with the electrons and nuclei of the target atoms through Coulombic (charged particle) interactions. During interactions with electrons, target atoms are ionized by ejection of inner-shell electrons, and x rays are released as the affected atoms regain stability by reordering of the electron shells. These x rays are termed "characteristic" x rays because their energy is characteristic of the type of metal employed as the x-ray target. For example, characteristic x rays of 58 and 67 keV are released from a tungsten target, where keV stands for kilo-electron volt, and the electron

volt is a unit of energy equal to that gained by an electron accelerated through a potential difference of 1 V.

As electrons interact with nuclei of the target atoms, they are slowed down, and energy is released in the form of x rays termed bremsstrahlung (braking radiation). Bremsstrahlung provides a continuum of x-ray energies with a maximum value defined by the energy of the impinging electrons. For most x-ray beams used for medical imaging, bremsstrahlung is a more important contributor compared with characteristic x rays. A notable exception is the significant role played by characteristic x rays in beams employed for mammography (imaging of breast tissue), an application discussed later in this article.

To prevent the accelerated electrons from interacting with gas molecules on their way to the target, components of the x-ray tube are housed in a glass tube that is evacuated to very low pressure. The tube is contained within an oil-filled shielded housing that provides electrical insulation and prevents x rays from emerging in unwanted directions. During an x-ray exposure, the technique factors [tube voltage (kVp), tube current (mA), and exposure time (ms)] are monitored carefully to prevent overheating of the target and other components of the x-ray tube.

Interactions of X-Rays. For a parallel, monoenergetic beam of x rays, the intensity I of x rays transmitted through a material of thickness z is

$$I = I_0 \exp\left[-\int \mu(z)dz\right],$$

where the line integral is taken over all tissues along the x-ray beam, I_0 is the intensity with no material present, and μ is the linear x-ray attenuation coefficient of the material, which may vary depending on the material's composition at each depth. If the material varies in composition laterally from one point to the next, the transmitted x rays also vary in intensity across the x-ray beam. By capturing the transmitted x-ray beam on a film or fluorescent screen, the pattern of variation in the material's composition is reflected in the image. As mentioned earlier, this image is termed a projection radiograph because it is formed through projection of a material into an image by transmitted x rays.

The linear attenuation coefficient μ is the sum of coefficients for various types of x-ray interactions that may occur in the material. For the energy range (20–150 keV) of x-ray energies used to produce medical images, two types of interactions are dominant. These interactions are the photoelectric effect, and the Compton Effect. The dependence of these coefficients on x-ray energy is shown in Fig. 2 for interactions in human soft tissue.

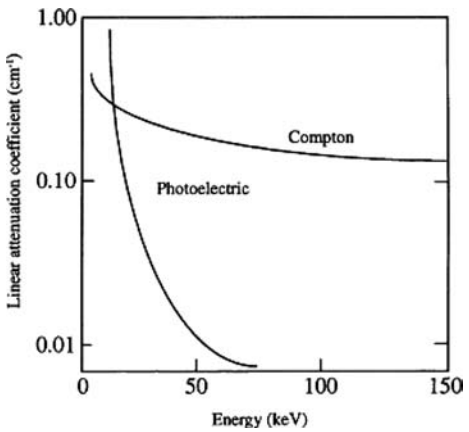

Fig. 2. The linear attenuation coefficient for x rays in soft tissue is the sum of two dominating contributions. Attenuation coefficients for these two contributions, Compton scattering and photoelectric absorption, are plotted as functions of the x-ray energy.

In a photoelectric interaction, the x ray interacts almost always with a tightly bound electron in an inner shell of an atom of the absorbing material. Because of the importance of tightly bound electrons, photoelectric interactions are strongly influenced by the atomic number Z, with the probability of photoelectric interaction per unit mass of material varying directly with Z^3 of the material. All of the energy of the x ray is transferred to the electron, which is ejected from the atom with a kinetic energy E_k of

$$E_k = E_{\text{x-ray}} - E_b,$$

where E_b is the binding energy of the ejected electron and $E_{\text{x-ray}}$ is the x-ray energy, which can also be expressed as hv, where h is Planck's constant (6.62×10^{-34}J-s) and v is the frequency of the x ray. Since the x ray is only energy, it disappears during a photoelectric interaction and is essentially replaced by a high-speed electron and an ionized atom. Photoelectric interactions occur predominantly with low-energy x rays, and decrease in likelihood as (hv)−3. A photoelectric interaction is depicted in Fig. 3(a).

A Compton interaction results in the scattering of an x ray in a new direction at reduced energy, rather than complete absorption of the x ray. Compton scattering produces most of the scattered radiation that degrades the quality of x-ray images. In this type of interaction, the x ray interacts with a loosely bound electron in an outer shell of an atom of the absorbing material. The electron is ejected with an energy equal to the difference in energy of the incoming and scattered x rays, with the assumption that the binding energy of the ejected electron is so small it can be neglected. Because the interaction occurs almost always with outer, loosely bound electrons, the Compton interaction is independent of the atomic number Z of the absorbing material. Compton interactions occur predominantly for the higher range of x-ray energies employed for medical imaging. The likelihood of these interactions decreases gradually with increasing x-ray energy. A Compton interaction is depicted in Fig. 3(b).

For both photoelectric and Compton interactions, the linear attenuation coefficient varies with the physical density (kg/m^3) of the absorbing material. Hence, the intensity of x rays transmitted through a material reflects the density of the material and, to varying degrees, the atomic number of the material, depending on the energy of the x rays and, therefore, the degree to which photoelectric interactions are responsible for reducing the intensity. By choosing the x-ray energy through selection of the voltage across the x-ray tube, an x-ray beam may yield a projected radiograph that accentuates or suppresses differences in atomic number among different constituents of an absorbing material. This characteristic is used to great advantage in medical imaging. For example, low-energy x rays may be used to amplify small differences in tissue composition that may be important for the detection of subtle abnormalities in soft tissue. Breast imaging is one example where low-energy x rays are used to amplify subtle soft-tissue differences. On the other hand, high-energy x rays may be needed to suppress relatively large differences in tissue composition so that more subtle features of tissue are not hidden by "shadows" cast by strongly absorbing structures. Chest imaging is one example where high energy x rays are used to penetrate the ribs and other strongly absorbing structures to reveal more subtle features of the underlying lung parenchyma. For x rays at any energy, those that are not transmitted through the patient are absorbed or scattered in the patient. These processes result in energy deposition in the tissues of the patient, where the energy deposited per unit mass of tissue is known as the "absorbed dose."

Image Production on Screens and Film. Image receptors employed for x-ray imaging include film, usually used in combination with fluorescent screens; fluorescent screens contained within an image intensifier for fluoroscopic imaging of dynamic processes; and solid-state detectors such as semiconductor detectors and photostimulatable phosphorescent plates for generation of electronic signals. Photographic emulsions are sensitive to x rays, and an x-ray image of exceptionally high quality can be formed by direct exposure of photographic film to an x-ray beam. This approach to medical imaging is occasionally used when exquisite detail is required in the image, as might be the case when hairline fractures in the bones of extremities are suspected. However, film by itself is an inefficient absorber of x rays, and for most applications it would require long exposure times that would yield images with unacceptable amounts of motion blurring. In almost all cases, permanent x-ray images are produced by sandwiching the film between "intensifying screens" that absorb x rays with reasonable efficiency (up to 50%) and emit visible light that in turn exposes the photographic film.

Most x-ray images are produced by sandwiching an x-ray film between intensifying screens in an imaging cassette that is tightly sealed (sometimes even evacuated) to produce intimate contact between the film and screens,

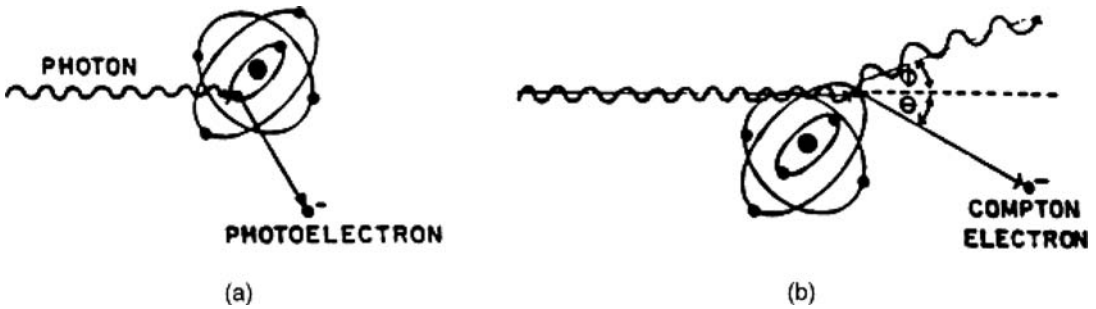

Fig. 3. (a) Photoelectric interaction; (b) Compton scattering.

thereby reducing geometric blurring. Cassettes are available to hold film of different sizes from 4×4 inches to (10×10 centimeters) 14×17 inches (35.6×43 centimeters) used for chest radiography. Once the film has been exposed to x rays or light from the intensifying screens, it contains a "latent image" that can be made visible by chemical processing. In the visible image, darker areas represent regions penetrated by a larger number of x rays, whereas lighter areas depict regions where more x rays are absorbed. In many cases, the lighter areas reveal bony structures because the higher density and atomic number of bone results in greater absorption of the impinging x rays.

Fluoroscopy. Projection radiography yields exquisite images that represent a "snapshot in time" of the patient's anatomy. In many cases these images are sufficient to detect an abnormal condition and to arrive at a diagnosis of the cause of the abnormality. But this is not true in all cases. Sometimes a continuous image is required that yields information about how the region of anatomy is changing or functioning over the course of a few seconds or minutes. The technique that yields such a continuous image is referred to as "fluoroscopy" because it captures the image instantaneously on a fluorescent screen and displays it in real time to the viewer.

Early applications of fluoroscopy employed a fluorescent screen that was viewed directly by the physician. The image was so dim, however, that the observer's vision had to be "dark-adapted," and even then only gross features could be detected. The viewing conditions resembled those present in a darkened movie theater. Although this approach was highly unsatisfactory, it was the only method available for fluoroscopy until the 1950s when the image intensifier was developed.

An image intensifier is depicted in Fig. 4. X rays impinging on the CsI input screen produce light that dislodges electrons from the photocathode. These electrons are accelerated toward the anode and are focused to pass through the aperture in this structure and onto the output screen. Here they produce a minified image that is thousands of times brighter than the image on the input screen. This image may be captured optically and projected through a system of lenses and mirrors for direct viewing by the observer. More often it is projected into a television camera and converted into an electrical signal that can be transmitted to a remote television monitor for reconfiguration and viewing. Since the image is converted from light to an electrical signal during this process, it can be converted easily to a digital image for integration into a digital imaging network.

Fluoroscopic methods are an essential part of medical x-ray imaging. They are widely employed in many types of x-ray studies, including those of the gastrointestinal tract and angiographic studies of the central and peripheral circulatory system. They also are used for image-guided therapy (e.g., coronary angioplasty, interventional neuroradiology, and minimally invasive surgery), a therapeutic approach that is growing rapidly in application because of its reduced morbidity and, often, lower cost compared with alternative therapeutic approaches.

Digital Imaging. The combination of intensifying screens and photographic film has many advantages for capturing and recording x-ray images. It is simple, portable, and inexpensive, and it yields images with excellent anatomic detail. This approach, however, has some disadvantages as well. It is limited to a rather narrow range of acceptable exposures and offers little flexibility for image enhancement or data compression. Film images are bulky to store and easy to misplace, and they must be transported physically from one location to another. Replacing this analog method of image production with an approach that yields digital images would eliminate these disadvantages. Hence, considerable interest in digital approaches to projection radiography has surfaced in recent years. In all likelihood, digital methods will capture an increasing fraction of the projection radiography market over the next several years.

In the digital radiographic unit the x-ray source and receptor are computer controlled to yield digital images that are displayed in real time on a video screen. Digital images can be stored on magnetic media or optical disk, and a film-writing device can be used to produce permanent analog copies of the images if they are needed. Two types of image receptors currently are used in digital radiography. One type records the entire image simultaneously, while the other acquires a complete image by scanning the x-ray beam and receptor in synchrony across the patient, a technique known as scan-projection radiography. Various methods are employed for digital data acquisition, including the use of image intensifiers with frame-grabbing television cameras, ionographic chambers, solid-state detector arrays, and photostimulated-luminescence plates.

Conventional projection radiographic films can be digitized with a scanning micro-densitometer to yield digital radiographs. As with any other digital image, a digital radiograph can be transmitted electronically to distant sites for interpretation and consultation, a technique known as teleradiology. Digital radiographs can be integrated with other digital images into an electronic image network for correlation with other digital images such as those produced by computed tomographic techniques, as discussed later.

Digital x-ray images offer several advantages over screen and film radiographs. They can be computer-processed to highlight selected features (edge sharpening, contrast enhancement, and noise smoothing), and the data can be compressed for efficient transmission electronically to distant sites. They require less storage space, and copies can be easily presented for viewing without risk of misplacing the original data. Digital x-ray images sometimes require less radiation exposure compared with analog projection radiographs. Finally, computer subtraction of digital images taken at different times can often reveal changes that are not visible in the original images. Disadvantages of digital radiographs include the cost of the equipment required for their production compared with simple film-screen techniques and possible losses in image detail occasioned by the finite number of picture elements (pixels) used for image display.

Image Detail. The level of detail visible in an x-ray image is a compromise among four kinds of resolution: spatial, contrast, temporal, and statistical. Spatial resolution is related to the geometry of the image-forming process and the resolving capacity of the imaging device (often called the "image receptor"). Contrast resolution is affected by the differences in the absorption and scattering characteristics of the various tissues depicted in the image and by the impact of scattered x rays on the receptor. Temporal resolution refers to the blurring caused by the patient's voluntary or involuntary movement (e.g., breathing, peristalsis, cardiac motion, or vascular pulsatile motion) during exposure to x rays. Statistical resolution is related to the number of x rays absorbed in the receptor to produce the image; the noise is inversely proportional to the square root of the number of x rays used to form the image.

The challenge of x-ray imaging is to capture subtle differences (i.e., modulation) in tissue composition by passing an x-ray beam through the tissue, and to transfer these captured differences onto an image receptor where they can be seen by the human eye. That is, the purpose of medical imaging is to transfer modulation in the tissue (object) into modulation in

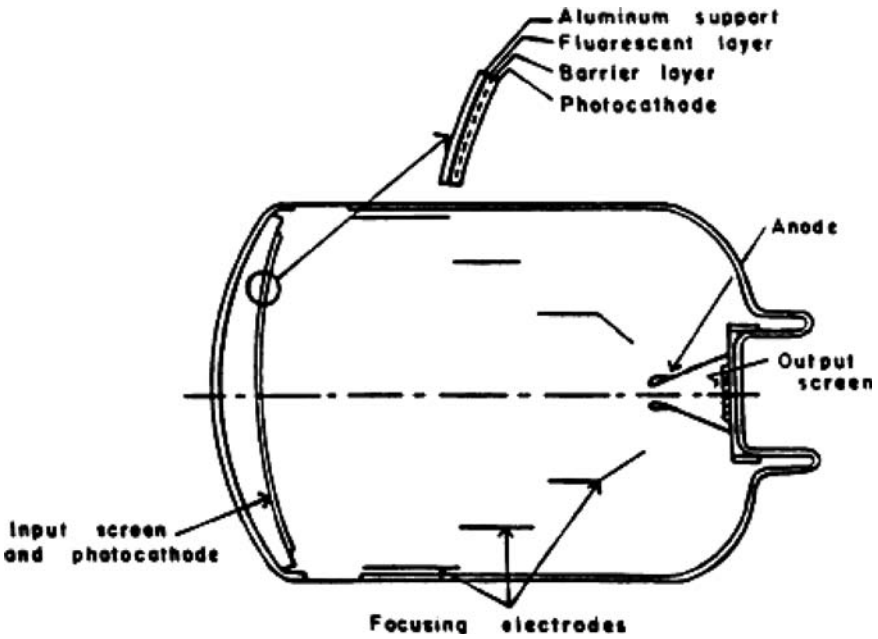

Fig. 4. X-ray image intensifier.

the image. The degree to which this modulation is transferred faithfully by an imaging system is described as its modulation transfer function (MTF). With most imaging systems, object modulation can be transferred to the image with high fidelity if the modulation is of relatively low frequency (i.e., the object is composed of relatively large structures that are well separated from adjacent structures). For smaller structures that are closer together, however, the integrity of modulation transfer may be less exact. Hence, the MTF is frequency dependent, as shown in Fig. 5 for two imaging systems. In this illustration, the fidelity of system 1 is superior to that of system 2, as evidenced by the higher values of MTF at higher frequencies.

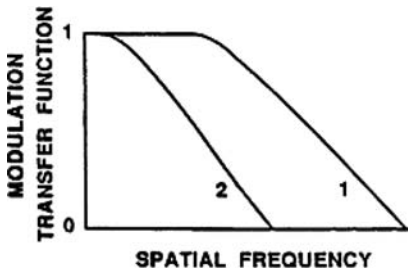

Fig. 5. Modulation transfer function (MTF) for two x-ray imaging systems, with system 1 providing higher spatial fidelity compared with system 2.

The MTF is a relatively simple (and somewhat simplistic) measure of the performance of an imaging system. To determine the MTF, one obtains an x-ray image of a very thin transparent slit in an otherwise opaque object. The image of the slit is scanned with a microdensitometer to determine the spread of the slit in the image. The resulting curve is described by a "line spread function" that can be characterized in frequency space through the process of Fourier transformation. The result is the MTF, expressed as a function of spatial frequency, as demonstrated in Fig. 5. The spatial frequency, expressed in units such as line pairs per millimeter or cycles per millimeter, is a measure of the frequency of variation per unit distance. It may be compared with the temporal frequency, expressed in units such as cycles per second or hertz, which is a measure of the frequency of variation per unit time.

Image Interpretation

Interpretation of medical images is a complex process that is as much art as science. It requires years of training, much of which is provided in a "master and apprentice" style since it has not been possible to model the interpretive process quantitatively. On the other hand, computer programs have been written to perform selected analyses of the patterns of information present in certain types of images such as chest radiographs and mammograms. By comparing these analyses to databases compiled from a large number of normal and abnormal images, a tentative diagnosis can be arrived at for presentation to the interpreter for confirmation. Such a decision-support system is referred to as "computer-aided diagnosis." Studies of this approach have shown that it increases the accuracy of diagnosis of the typical radiologist (Doi et al., 1993).

Computer-aided diagnosis is a far step from the use of expert artificial-intelligence systems to provide a primary diagnosis from medical images without human intervention. Such systems would essentially have to mimic the thought processes of physicians interpreting images, including the incorporation of ancillary information such as the patient's history and data acquired by physical examination. These thought processes are largely intuitive, acquired through apprenticeship training and experience, and are almost impossible to articulate clearly. Replacement of the human interpreter of images with a computer algorithm for image interpretation would be a major challenge.

It is important to recognize, however, that an expert system for image interpretation does not have to be perfect. Instead, it must function only at a level at least comparable to the accuracy of the average radiologist. With this criterion in mind, exploration is occurring of expert systems for image interpretation in medicine. Some of these explorations employ "neural networks," algorithms that use feedback information from humans to build decision rules based on the successes and failures of past decisions. Medical imaging is still a long way from automated diagnosis, as contrasted with computer-aided diagnosis, which relies ultimately on human confirmation or rejection of a proposed diagnosis. Still, progress in expert systems in other imaging disciplines, including military surveillance and space exploration, has been spectacular over the past two decades, and the application of such systems to medical imaging remains promising. See also **Artificial Intelligence: Neural Networks**.

X-Ray Tomography

In a conventional radiograph, all structures within a three-dimensional volume of tissue exposed to X rays are projected "in focus" onto the two-dimensional image receptor. As a result, an anatomic structure of interest is often obscured in the image by the shadow of objects that lie above or below it in the patient. Removing the presence of these obscuring shadows often helps reveal the structure of interest. Two approaches, analog tomography and computed tomography, are available for removing the image of obscuring structures. As computed tomography has grown over the past two decades, analog tomography has diminished in popularity.

Analog Tomography. Analog tomographic images are produced by keeping structures in focus in a selected image plane in the patient, while blurring the image of structures above and below the imaging plane. The blurring is accomplished by moving the X-ray tube and image receptor during exposure through an angle with a pivot (fulcrum) in the image plane. In actuality, the image plane has a finite thickness (and is more properly referred to as an image section) that can be reduced by increasing the angle of motion. The location of the section within the patient may be changed by positioning the patient appropriately with respect to the pivot of the tomographic angle. Although the shadows of overlying and underlying structures are blurred, they are not completely removed from the image, and they frequently appear as "ghostlike" artifacts that interfere with the clarity of structures of interest. In addition, analog tomography has the limitations that conventional image receptors are unable to resolve small differences (1–2%) in the intensity of incident radiation, and the wide-area x-ray beams employed produced considerable scattered radiation that interferes with the visualization of subtle detail in the image. Analog tomography is still used for certain applications such as a supplement to chest radiography. For other tomographic needs, however, it has been replaced by computed tomography because this approach reduces the limitations often encountered with conventional tomography.

Computed Tomography. The mathematical model used in computed tomography (CT) was described in 1917 in a remarkable work by the Austrian mathematician Radon (Radon, 1917). The model was first used in applications of image reconstruction to radio astronomy, electron microscopy, and optics. In 1972, the first commercially available x-ray transmission CT unit for studies of human anatomy was announced. In 1979, the developer of this unit, G. Hounsfield 1973, shared the Nobel Prize in Medicine with a physicist, A. Cormack 1963, who did early work on image reconstruction. The first commercial CT unit employed a narrow beam of x rays scanned across the patient in synchrony with a scintillation detector moving on the opposite side of the patient. The intensity I of x rays measured by the detector is given by

$$I = I_0 \exp\left(-\sum \mu_i x_i\right),$$

where μ_i represents the linear attenuation coefficient of each of several structures in the path of the narrow x-ray beam and x_i represents the thickness of each of the structures.

With a single measurement of X-ray transmission, the separate attenuation coefficients cannot be determined. With multiple transmission measurements obtained at different orientations, however, the separate coefficients can be distinguished to yield a two-dimensional distribution of linear attenuation coefficients across the imaging section defined by the thickness of the scanning X-ray beam. This distribution can be mapped as CT numbers determined from the formula

$$\text{CT number} = 1000(\mu - \mu_w)/\mu_w,$$

where μ is the coefficient at a specific location in the section and μ_w is the linear attenuation coefficient of water for the x-ray energy employed for CT scanning. From this expression it can be appreciated that the CT number for water is zero and the CT number for air, with a very small value of μ, is close to -1000. The CT number would be about $+1000$ for a structure such as compact bone or colon containing barium contrast medium, because the physical density would be almost twice that of water. The CT numbers can be presented as various shades of gray to provide a visual display of the distribution of tissues across the image section. This display is referred to as a CT image.

The X-ray tube and scintillation detector of early CT units scanned the patient along a linear path perpendicular to the axis of rotation of tube and detector. Measurements of x-ray transmission were obtained every 2.5 mm (0.09843 in) over the linear path of 40 cm (15.75 inches) length to yield a total of 160 transmission measurements. Then the angular positions of the x-ray tube and detector were advanced 1°, and another scan of 160 measurements was obtained. This process was continued over 180° to provide 28 800 transmission measurements. These data were then transmitted to a computer equipped with a mathematical package for reconstructing a cross-sectional image of the scanned section. Initially, reconstructed images were computed by a time-consuming iterative mathematical model. More recently, faster algorithms using a convolution (filtered back-projection) model for image reconstruction have been employed (Kak and Slaney, 1988). These algorithms rely on a Fourier transformation of x-ray projection data into frequency space, permitting use of ramp and cutoff-frequency filters to improve image quality and enhance subtle features in the image. See also **Fourier Transform**.

The combination of translational and rotational motion employed in early CT units yielded satisfactory CT images, but several minutes were required for data acquisition, limiting the method to studies of structures such as the head and extremities where voluntary and involuntary motion of the patient is not a problem. There was great interest in applying CT to thoracic and abdominal studies, but the scan time had to be decreased from minutes to seconds if these areas were to yield satisfactory images. Major efforts to reduce scan time led to the development of successive generations of CT scanners as depicted in Fig. 6. The initial translate-rotate scanner (first generation) is shown in Fig. 6(a), whereas an array of detectors (second generation) that tracks the linear motion of the x-ray beam is shown in Fig. 6(b). A purely rotational design (third generation) for CT scanning is depicted in Fig. 6(c), and a fourth-generation design is shown in Fig. 6(d) in which an X-ray tube rotates around the patient within a stationary ring of X-ray detectors. With the rotational scanners, data for a single section can be acquired in just a few seconds. By combining these geometries with the patient gantry moving continuously along its long axis, cross-sectional images of many slices can be obtained in minimum time, a process known as "spiral" or "helical" scanning (Heath et al., 1995). Finally, images of vertical (sagittal or coronal) slices through the body can be produced by compiling arrays of attenuation coefficients along axes parallel to the patient's long axis.

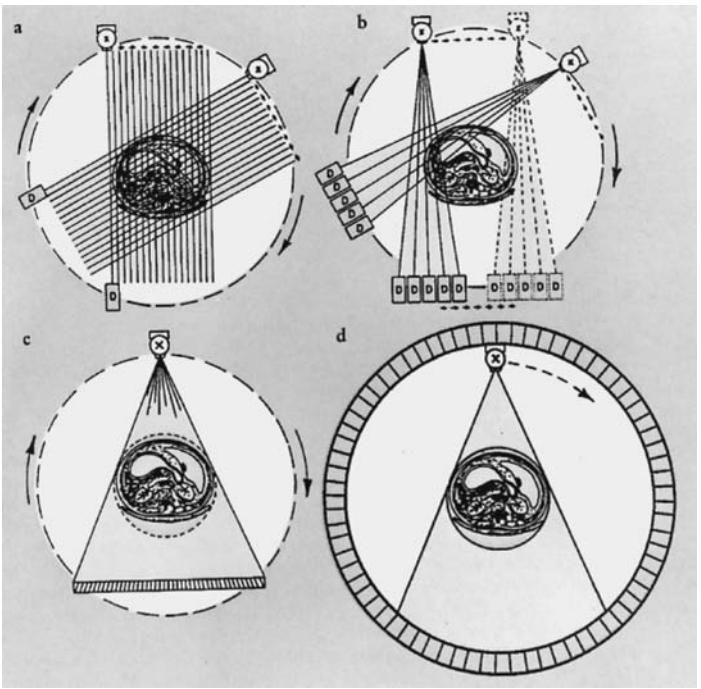

Fig. 6. Evolution of geometries of x-ray CT scanners. (**a**) First-generation scanner, in which the pencil x-ray beam is both translated and rotated to cover the region of the body being imaged; (**b**) second-generation scanner, with a diverging fan beam and detector array that are translated and rotated; (**c**) third-generation scanner, with a fan-beam source that rotates around the body, together with its detector bank; (**d**) fourth-generation scanner, with a rotating fan-beam source and a stationary ring of detectors.

Although the evolution of CT scanning geometries shortened the time to acquire images, none of the geometries permitted data acquisition in a time (less than 0.1 s) short enough to capture images of the heart and other blood-perfused organs without significant degradation caused by motion. For CT images of these organs, a way is needed to produce x-ray projection data without mechanical motion in the scanner. A scanner of this sort is known as a fifth-generation scanner (Hendee, 1983). It employs an electron-beam gun that generates x-ray beams in different directions by

scanning over a stationary concave metal target. The resulting scan times are as fast as 50–100 ms.

CT images are most commonly displayed as cross-sectional representations of patient anatomy. By examining continuous cross-sectional images, radiologists can intuitively integrate the imaging information into a three-dimensional model of anatomy. This integration can also be accomplished physically by recognizing that a data set of contiguous two-dimensional sections in computer memory is in actuality a three-dimensional database. By mathematically compiling data across planes that cut across this database in preferred directions, coronal and sagittal images, as well as images at oblique angles, can be produced. Furthermore, the three-dimensional database can be analyzed to yield images that give the distinct impression of being three-dimensional. They also can be windowed to yield images of specific ranges of CT numbers corresponding to selected types of tissue (Fishman et al.,1989).

Image Networking

Medical imaging includes several systems, including x-ray computed tomography and magnetic resonance imaging, that present imaging data in a digital format. Linking these systems electronically in a picture archiving and communications system (PACS) [referred to as an image management, archiving and communication system (IMACS) when connected into other information networks such as the radiology and hospital information systems] offers several advantages, including these: images can be stored electronically in a central location, images from different systems can be called up for display and comparison in a viewing center, and images can be transmitted to remote locations for viewing by specialists without loss of the central file of data. A PACS has the potential of expediting diagnoses, improving diagnostic accuracy, enhancing information to other physicians, and eliminating misplaced and lost films. With the availability of digital x-ray imaging methods, PACS can be expanded to encompass essentially all imaging systems employed in medicine. Many leaders in medical imaging believe that a fully integrated PACS represents the radiology department of the future. Others are convinced that the expense of converting fully to a PACS (several million dollars for a typical imaging facility) will prevent most departments from converting completely to PACS, at least in the near future. Instead, they believe their conversion will occur incrementally, with film remaining as the preferred detector for some applications (e.g., mammography and chest imaging) for some time to come. See also **Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI)**.

Applications

The use of X-rays is so ubiquitous in medicine that almost everyone has had an x-ray examination. Most examinations are for routine purposes such as to detect dental caries, confirm that a fractured bone has been set properly, provide a routine examination of the chest to rule out pneumonia, or perform a barium swallow or enema to study the integrity of the gastrointestinal tract. Many more applications of X-rays to medicine exist, however. Even though these applications may be encountered less frequently, they are critically important to the patients who need them. Two specific applications are described here as examples of the many interesting challenges presented to physicists and engineers working in the discipline of medical physics.

Mammography. One of every eight women will develop breast cancer in her lifetime, and many will die as a result. The most effective measure against this disease is periodic screening of the breasts with x rays for detection of cancer before it has a chance to spread. Many voluntary and professional organizations recommend annual screening with X-rays for women 50 years of age and older, and some recommend screening every 1 to 2 years for women between 40 and 50 years of age. X-ray imaging of the breasts is referred to as mammography. See also **Cancer and Oncology**.

A mammographic X-ray image must be able to reveal very subtle differences in the composition of soft tissues of the breast, as well as the presence of tiny ($<100\ \mu m$) specks of calcium hydroxyapatite (calcifications) that suggest the presence of malignant cells. That is, mammographic images must bring out very small variations in contrast and must also yield exquisite detail within a background of relatively low noise. These images must depict the relatively thick tissues near the chest wall without losing detail in thinner regions of the breast. These demands place inordinate requirements on systems for production of satisfactory mammographic images. They also necessitate periodic evaluation of image quality and radiation dose by a physicist experienced in inspection and quality control of mammographic units (American College of Radiology, 1993).

Subject contrast is enhanced in mammography by the use of low-energy x rays that interact strongly by photoelectric processes. Reliance on these interactions yields the greatest difference in transmission among structures that are similar, although not identical, in chemical composition. The use of low-energy X-rays also aids in the identification of calcifications. In most cases today, mammography is performed with special x-ray units that employ an X-ray tube operated at 20–35 kVp and a film and single-screen image receptor designed specifically for mammography. The x-ray tube has a molybdenum target that produces characteristic K x rays of 17.4 and 19.8 keV superimposed on a bremsstrahlung x-ray spectrum with a maximum energy equal numerically to the peak voltage expressed as kVp. The x-ray beam is filtered with a thin sheet of molybdenum that is relatively transparent to the characteristic x rays but absorbs higher-energy x rays with high efficiency because of the existence of the K absorption edge above 20 keV.

Screen–film mammography is an exquisitely sensitive and useful imaging method. Still, it may be possible to improve breast imaging by replacing screen-film receptors with digital detectors. Unlike film, digital systems acquire, display, and store images independently, so that each of these functions can be optimized without interfering with the others. Also unlike film, the response of digital detectors varies linearly over a wide range of exposures. In addition, digital images can be "windowed" to enhance the contrast of specific regions of tissue. Both of these attributes of digital detectors improve the contrast sensitivity of digital mammographic methods compared with analog screen–film methods. These advantages may well outweigh the disadvantage of a slightly lower spatial resolution with digital methods. Although digital detectors have high potential, the practicality, dependability, and low cost of film continue to make it the preferred detector for mammography in clinical settings.

Radiation can induce cancer as well as detect it. (Radiation can also be used to treat cancer, which is the medical specialty of radiation oncology.) In the past, concern has been expressed that screening large numbers of asymptomatic women for breast cancer could induce as many cancers as are cured through the process of early detection. This concern was primarily a result of the relatively high doses delivered to patients with earlier, less sensitive methods of image production. With today's ultrasensitive screen–film combinations, together with the use of low-energy, highly filtered x-ray beams, the induction of cancer is much less likely. The overwhelming balance of benefit over risk in screening programs for older women has largely dispelled concern over the possible induction of cancer in the screened women (Kimme-Smith, 1992). Nevertheless, efforts to reduce radiation dose further in mammography should be continued until each examination uses no more than the essential number of x rays to reveal underlying pathology.

X-Ray Treatment Planning. Cancer is characterized by an abnormally rapid proliferation of cells. The successful treatment of cancer with X-rays requires that the cancer is localized and that that cancer and its microscopic extensions into normal tissue receive a dose of radiation sufficient to kill the cancer cells. At the same time the dose to nearby normal tissues must be kept low enough to avoid serious complications. The balance between these doses is depicted in Fig. 7 (Wolbarst,1988). The probability $P_{tumor}(D)$ that the cancer will be controlled by killing tumor cells increases with D, the radiation dose. The probability $P_{\text{organ}}(D)$ that life-threatening complications from radiation damage can be avoided is, of course, a decreasing function of D. The probability $P_{\text{patient}}(D)$ that the patient will survive both the disease and the treatment is

$$P_{\text{patient}}(D) = P_{\text{tumor}}(D) \times P_{\text{organ}}(D).$$

The patient's survival probability as a function of radiation dose is the lower curve in Fig. 7. If the dose is low, the tumor is likely to recur. At high doses, the therapy itself is likely to cause unacceptable complications, perhaps threatening the patient's life. Between these extremes the physician seeks to maximize the patient's survival of both the cancer and the treatment. If the radiation dose that optimizes the balance between curative treatment and complications is so high that the patient experiences extreme

$$P_{\text{patient}}(D) = P_{\text{tumor}}(D) \times P_{\text{organ}}(D).$$

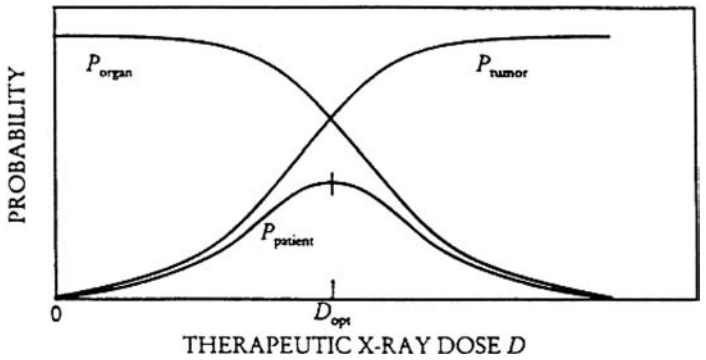

Fig. 7. Therapeutic outcome probabilities for cancer patients undergoing x-ray treatment, plotted schematically as functions of radiation dose D. The probability of success (P_{patient}) is the product of the probability that the tumor will be destroyed (P_{tumor}) and the probability (P_{organ}) that the treatment will not cause life-threatening damage to normal tissue.

discomfort, the physician may be forced to settle for a lower dose even though the patient's chance of surviving the cancer is reduced.

Radiation-dose optimization demands accurate delineation of the margins of the cancer. That in turn demands good medical imaging. Before CT, cancer localization and treatment planning depended principally upon projection radiography combined with clinical and surgical (if available) information about the patient, together with knowledge of the natural course of the disease. But projection radiography has many disadvantages. It is frequently hard to see the cancer clearly, and it is often difficult to transcribe the radiographic information onto a cross-sectional plane through the patient for designing the treatment plan describing the orientation and relative weighting of radiation beams used for treatment.

CT and, more recently, magnetic resonance imaging have largely overcome these problems. Many treatment centers have a CT unit dedicated to treatment planning and monitoring. The images provide not only a cross-sectional picture of the patient's anatomy, including the cancer and surrounding tissues, but also an accurate representation of the body contour and organs that are particularly sensitive to radiation. Because the data are digital, they can be entered immediately into the treatment-planning computer so that proposed treatment plans can be superimposed directly onto the CT images. Once an acceptable plan is accepted, it can be implemented on the x-ray treatment machine. This entire procedure must be carefully monitored to ensure that no misalignment occurs and that the treatment plan accurately reflects the radiation administered during treatment. Monitoring of this process is the responsibility of the medical physicist.

In most radiation therapy centers, commercial imaging units are used to generate CT information for treatment planning. In an effort to improve alignment of the CT information with the treatment geometry, a few medical physicists have built CT scanners on treatment-simulating gantries. Although these units yield spatial resolution inferior to that with commercial CT units, they duplicate the treatment geometry and provide images good enough to be useful for treatment planning.

Most X-ray treatments involve the use of multiple fixed radiation fields converging on the cancer from different directions. In this manner the dose is concentrated in the cancer while much lower doses are administered to surrounding normal tissues. In some cases a better dose distribution can be achieved by continually rotating the gantry of the treatment machine around the patient during treatment so that only the cancer is constantly in the path of the x-ray beam. One complication is that cancers are almost always asymmetrical. Therefore, the size of the x-ray beam must be expanded or contracted continuously during rotation. The dose distribution could be improved even more by simultaneously varying the dose rate during rotation. This approach, termed "conformal therapy," is being pursued in several centers in the United States and overseas (Mageras et al., 1994). It requires detailed three-dimensional knowledge of the anatomy of the irradiated tissue, together with exquisite computerized control of the x-ray unit itself, as well as the x-ray gantry and patient couch position.

X-RAY SCAN AND OTHER MEDICAL IMAGERY. Medical imaging conventionally refers to the non invasive or minimally invasive techniques employed to view internal organs of the body, typically for diagnosing disease. In a broader sense, it refers to a field that enables acquisition, processing, analysis, transmission, storage, display, and archiving of images of internal body parts for interpretation and patient management (diagnosis, disease staging and evaluation, treatment planning and follow-up). Medical imaging was practically born with the discovery of the X-rays by W. C. Roentgen in 1895 and has since based its success on observation and the accumulated experience of the examining physician. See also **X-Ray**; and **X-Ray Analysis**.

Molecular imaging is a natural out grown of the medical imaging field. Recent advances in molecular biology have resulted in an improved understanding of many disease and natural processes. Consequently, molecular imaging links the empirical diagnostics and experimentally tried treatment management protocols with the fundamental understanding of the underlying processes that generate the observed results. As discoveries of the molecular basis of disease unfold, one top research priority is the development of imaging techniques to assess the molecular basis of cell dysfunction and of novel molecular therapy. Molecular imaging techniques are ideally based on technologies that have an intrinsically high resolution (spatial and temporal) and allow the detection of low concentrations of target biomolecules involved, such as nuclear medicine imaging (Positron Emission Tomography, PET; Single-Photon Emission Tomography, SPET), magnetic resonance imaging (MRI) and spectroscopy (MRS), optical tomography, autoradiography, or acoustical imaging. See also **Magnetic Resonance Imaging (MRI)**.

The examination of biochemical processes with an imaging technology is of vital importance for modern medicine. As, in most cases, the location and extent of a disease is unknown, the first objective is an efficient means of searching throughout the body to determine its location. Imaging is an extremely efficient process for accomplishing this aim, because

data are presented in pictorial form to the most efficient human sensory system for search, identification, and interpretation: the visual system. Recognition depends on the type of information in the image, both in terms of interpreting what it means and how sensitive it is to identifying the presence of disease.

Positron Emission Tomography (PET)

PET stands in the forefront of molecular imaging and allows the quantitative evaluation of the distribution of several pharmaceuticals in a target area *in vivo*. PET is a unique diagnostic imaging technique for measuring the metabolic activity of cells in the human body. It produces images of the body's basic biochemistry and biological activity in a noninvasive way, combining techniques applied in nuclear medicine with the precise localization achieved by computerized image reconstruction. PET is therefore a powerful diagnostic test that is having a major impact on the diagnosis and treatment of disease, as well as on patient management.

PET images can demonstrate pathological changes and detect and stage tumors long before they would be revealed with other conventional imaging modalities. Traditional diagnostic techniques, such as X-rays, computerized tomography (CT) scans, or MRI, produce anatomical images of what the internal organs look like. The premise with these techniques is that a visible structural change exists in anatomy caused by disease. However, biochemical processes are also altered with disease and may occur before a change in gross anatomy occurs. Furthermore, PET can provide medical doctors with important early information about very subtle changes of function in the brain and heart, due to disease-related modifications in tissue perfusion, cell metabolic rates heart disease, or neurological disorders (Alzheimer's, Parkinson's, epilepsy, dementia, etc.), allowing physicians to diagnose and treat these diseases earlier and, consequently, more efficiently and accurately, according to the axiom "the earlier the diagnosis, the better chance for treatment." PET can also help physicians monitor a patient's response to treatment, as well as identify distant metastases that can affect treatment, helping curtail ineffective treatments and reduce unnecessary invasive procedures. The field of PET has been emerging today into clinical diagnostic medicine and is approved by many insurance carriers for coverage.

PET scanning may help detect abnormal areas in your body. In particular, a PET scan may be used to detect or monitor.

Cancer. A PET scan can be particularly effective in identifying if you have cancer, if it has spread and if it has responded to treatment. Tumors often use more energy than healthy tissues do and may absorb more of a radioactive tracer, which allows the tumors to appear on the scan. In addition, PET scanning may be valuable in assessing the effectiveness of chemotherapy. PET scanning can also be used to determine the stage of a cancer. In the past, doctors could determine whether cancer had spread to the lymph nodes only if there was evidence of lymph node enlargement. With PET scanning, doctors may be able to detect cancer that has spread to a lymph node before enlargement occurs, allowing for a change to more appropriate treatment.

However, PET scan test results need to be interpreted carefully because noncancerous conditions can resemble cancer. Only a biopsy can confirm the presence of cancer.

Heart Problems. Doctors use PET scanning to detect areas of decreased blood flow in the heart. A PET scan may reveal early coronary artery disease and damaged or dead heart muscle due to a heart attack. It can also differentiate nonfunctioning dead heart muscle from poorly functioning heart muscle that would benefit from a procedure, such as heart surgery, angioplasty or coronary artery bypass surgery, to increase blood flow to heart muscle. A PET scan can be particularly important in people who've previously had heart attacks.

Depression. PET scanning allows doctors and scientists to compare brain activity in people experiencing periods of depression with brain activity in nondepressed people. Studies show that depressed people have less activity in certain brain regions than do people who aren't depressed. However, more research is needed to confirm this approach.

Alzheimer's Disease. A PET scan can detect mild physiological changes in the brain even when no signs or symptoms of Alzheimer's disease are evident and before severe damage to brain cells and memory loss occur. PET scanning can also provide visual images of activity in the brain when a person is asked to read, talk or listen to music. Such uses of a PET scan may help scientists to better understand the progression of Alzheimer's disease in different areas of the brain. PET scanning can also be a valuable tool in differentiating Alzheimer's disease from other types of dementia disorders, such as Parkinson's disease and Huntington's disease.

Genetic testing and PET scanning have been combined to examine the brains of middle-aged to older adults carrying a known genetic risk factor for Alzheimer's disease. Doctors and scientists are also combining PET scans with magnetic resonance imaging (MRI) to create three-dimensional images of the brain, making it possible to measure the rate at which various regions of the brain use, deposit and metabolize certain chemicals.

Other Brain Disorders. A PET scan can help locate the origin of abnormal brain activity associated with seizures due to epilepsy and assess brain function after a stroke. Doctors can also use a PET scan to detect memory disorders and certain mental health disorders, such as schizophrenia.

See also **Positron Emission Tomography (PET)**.

Computed Tomography (CT)

Introduction of computerized axial tomography in the form of the X-ray cat scanner (CAT) was a major event in the history of diagnostic medicine. The technology is also referred simply as computerized tomography (CT).

Tomography as a technique of X-ray photography by which a single selected plane is photographed, with the outline of structures in other planes eliminated, has been known for many years. X-rays lose energy in direct proportion to the density of the structure through which they pass. Thus dense structures of the body, such as bone, absorb much of the X-radiation and therefore in a traditional X-ray negative appear as light images — because less radiation has reached the film. The CAT scanner utilizes this same general principle (more or less energy absorbed, depending upon density of intervening tissue). But, instead of exposing a single X-ray film, or taking a series of single exposures from different angles and then comparing these in an attempt to create some semblance of the object in three dimensions, the CAT scanner indicates the exact amount of energy absorbed by the object from many different angles — so that the final image as seen by the radiologist is based upon a composite of contiguous one-millimeter cross sections. Film is replaced by electronic X-radiation detectors and the processing of so much information obtained in such a short time span is processed by a computer. A rapid rate of calculation is needed to measure tissue density, requiring the solution of about one-half million equations every few minutes.

The CAT scanner has been likened to a large doughnut that houses x-ray tube and detectors. The doughnut is positioned around the part of the patient to be examined. As the patient lies on a table, the doughnut, housed in a large gantry, rotates, creating images as it turns. When the X-ray beam passes through the body, it strikes a detector in which calcium fluoride crystals scintillate (flash light). These scintillations are transmitted to a computer as electric signals. While the computer processes the information, registering it on a cathode ray tube, the doughnut rotates a few degrees and repeats the process until it has completed a 180-degree arc around the patient. The scanner forms a grid of readings with innumerable X-rays creating a matrix of nearly 100,000 intersections as they enter from various angles. The average amount of X-radiation absorbed by a patient during a CAT scan is estimated to be about one-fifth that absorbed in X-ray exposures in a typical executive physical given by many clinics and hospitals over 40 years of age.

The result is an X-ray image that gives the illusion of three dimensionality. Because the CAT beam is rotated around the body, it can image organs that overlap and are therefore obscured under conventional x-rays or radiograms. By using several hundred X-ray detectors to produce one exposure, the CAT is an order of magnitude more sensitive to slight gradations in density than radiographs, which frequently do not allow the practitioner to distinguish between tissues of approximately the same density.

Prior to the CAT scanner, normal X-ray photographs of the brain tended to be blurred beyond recognition by the skull. Since the first application of the CAT scanner to brain imaging in 1972, the instrument has come to be considered an indispensable neurophysiological tool. Prior to the availability of the CAT technique, an image of the brain's complex vascular system was obtainable only by means of an angiogram or arteriogram.

Patients were given an injection of a dye directed to a specific site. In the diagnosis of some brain diseases, it was necessary to make a pneumoencephalogram ("air scan"), in which gas was injected into the lower spine and flowed upward to fill and outline brain cavities prior to x-ray procedures. These were both dangerous and painful procedures and required up to 2 or 3 days of hospitalization just for diagnostic purposes. The CAT can provide a detailed cross section of the brain in as brief a span as five minutes. Air scans can be eliminated and the need for angiograms has been sharply reduced. Rapid, usually accurate diagnosis of brain disorders and injuries has saved lives by reducing exploratory surgery and by greatly shortening delays in commencing treatment.

The image of an 80–90% underexposed medical radiograph can be increased to readable density and contrast by autoradiographic image intensification. The technique consists of combining the image silver of the radiograph with a radioactive compound, thiourea labeled with sulfur-35, and then making an autoradiograph from the activated negative.

Minimizing the X-ray dose received by patients during medical examinations and maximizing the quality of the radiographs are subjects of concern to the medical profession and the public. Some conflict is inherent in the two objectives because higher quality radiographs, i.e., those which convey more information to the physician, usually require higher exposure levels. Recent gains in quality or exposure reductions, or both, are due to developments, such as computer processing, electrostatic imaging systems, improvements in intensifying screens, and scatter rejection techniques.

Radiographs which are normally classified as "badly underexposed" actually contain most of the information which was intended to be recorded by the original exposure. Autoradiographic intensification effectively retrieves this information by increasing the image density and contrast to readable levels. The intensification occurs on an autoradiograph made from the underexposed film after the original image silver has been chemically combined with a radioactive isotope. See also **Computed Tomography (CT)**.

Other Photon Imaging Techniques

Since introduction of X-ray CAT scan technology, other photon imaging approaches have been developed. These concepts augment and, in some instances, are alternatives to the X-ray CAT scan. The more recent developments include positron emission tomography, K-edge dichromography, the use of synchrotron radiation, angiographic imaging, and nuclear magnetic resonance imaging. The latter topic is described in the article on **Nuclear Magnetic Resonance Spectroscopy (NMR)**. The recent use of synchrotron radiation is described under **Particles (Subatomic)**.

X-RAY STARS. See **Neutron Stars**.

X-RAY TECHNOLOGY. Analytical x-ray instruments are used to characterize materials in several different ways. As with medical x-ray instruments there are analytical instruments that can produce images of internal structures of objects that are opaque to visible light. There are instruments that can determine the chemical elemental composition of an object, that can identify the crystalline phases of a mixture of solids, and others that determine the complete atomic and molecular structure of a single crystal. These are the most common applications for x-ray instruments.

The determination of particle size and structural information for fibers and polymers, and the study of stress, texture, and thin films are applications that are growing in importance and can be examined with x-ray instruments.

Because of recent advances in hardware, particularly detector hardware, and computer software, x-ray instruments have become very powerful. Problems that could not be solved several years ago can be solved with the newer instrumentation. Also the instruments have become much more automatic so that the more routine problems can be solved much faster than a few years ago.

Characterization and Generation of X-Rays

X-Ray Electromagnetic Spectrum. X-rays are a form of electromagnetic radiation and have a wavelength, λ, much shorter than visible light. The center of the visible light spectrum has a wavelength of about 0.56×10^{-6} m. The energy of an x-ray photon expressed in kiloelectronvolts (1.0 keV=1000 eV) is related to wavelength expressed in nanometers (1.0 nm= 1.0×10^{-9} m) as follows:

$$E(\text{keV}) \approx 1.24/\lambda\ (\text{nm})$$

There are several ways to produce x-rays that have the range of energies appropriate for the various applications discussed here. The most commonly used methods are discussed below.

Synchrotron Radiation. X-rays are produced when very energetic electrons traveling close to the speed of light are decelerated. A continuous x-ray spectrum of intensity vs wavelength is produced. Very intense x-ray sources are available at synchrotron installations around the world. The Stanford Linear Accelerator in California is typical of these installations. Electrons are accelerated with electromagnets while traveling along a linear path of 2 miles. Then they are inserted into a nearly circular path which is maintained by bending magnets. In this circular path, the electrons lose energy by producing x-ray photons whose paths are tangential to the circle. X-ray instruments designed for many different applications are placed around the synchrotron ring.

Synchrotrons were originally designed for high energy particle physics studies. The synchrotron x-ray radiation was not desirable for those studies. Later synchrotrons were designed not for high energy particle physics studies, but instead were designed to optimize the desirable features of the x-ray and ultraviolet radiation produced. The so-called third-generation synchrotrons are the European Synchrotron Radiation Facility (ESRF) in Grenoble, France, The Advanced Photon Source (APS) at Argonne in the United States and the Super Photon Ring (Spring-8) in Harima, Japan. These facilities produce high energy x-ray beams at least 10,000 times brighter than the early synchrotrons. They have straight sections in their otherwise circular paths to allow the insertion of wiggler and undulator magnets. These magnets cause the electrons to oscillate in the plane of the ring causing a large increase in the intensity of the synchrotron radiation.

An undulator produces x-ray radiation as sharp peaks at several harmonics of some fundamental radiation energy. At higher magnetic field strength, the higher harmonics tend to smooth out producing a continuous and very intense spectrum of x-ray wavelengths. The insertion device operating under these conditions is called a wiggler.

X-Ray Tubes. X-ray tubes are the most widely used source for the generation of x-rays. In these tubes, electrons are accelerated by a high electric potential (20–120 kilovolts). These electrons strike the target (anode) of the tube. The electrons decelerate as they pass through the electron clouds of the atoms. This phenomenon produces a continuous spectrum similar, but much less intense, to that of the synchrotron. In addition, some high energy electrons knock electrons out of the atomic orbitals of the atoms of the target material. When these orbitals are refilled by electrons, x-ray photons are generated. The resulting x-ray spectrum

of intensity vs wavelength has a series of peaks known as characteristic lines. The wavelengths and intensities of these lines are dependent on the elemental composition of the target material (synchrotron radiation has no characteristic lines). The most intense peaks are the two lines known as $K_{\alpha 1}$ and $K_{\alpha 2}$ (or together known as K_{α}). The next most intense lines are the K_{β} lines.

Unlike for synchrotron radiation, the maximum intensity of x-rays from an x-ray tube is limited by how fast heat can be removed from the target to prevent its melting. In a conventional sealed tube, the target is stationary, relatively small, and must be continually cooled with water. In a rotating anode tube, the target is larger and is continually rotated so that the heat can be distributed over a larger surface. With such a tube the amount of heat, and hence, the intensity of x-rays can be greater than in a stationary target tube.

The materials that are used as targets in x-ray tubes depend on the application.

Properties of X-Rays. X-rays impinging on an object interact primarily with the electrons in the object, ie, there is very little interaction with the atomic nuclei that comprise most of the mass of the object.

An x-ray photon can interact with an object in the following ways:

1. The x-ray photon does not interact and is transmitted through the object in the same direction that it impinged on the object. The energy of the photon does not change.
2. The x-ray photon is completely absorbed. No x-ray photon leaves the object. All of the energy of the x-ray photon is transferred to the electrons within the object.
3. The x-ray photon is absorbed and another x-ray photon of longer wavelength (lower energy) is produced. In this process an electron (or electrons) gain the lost energy. The new x-ray photon may travel in any direction from the site of the event. This phenomenon is known as incoherent, inelastic, or Compton scattering. Because there is a transfer of energy at a localized position within the object the incident x-ray photon can be considered to behave as a particle.
4. The x-ray photon produces an oscillating electric field in the object. This electric field in turn causes a photon of the same wavelength as the original photon to be generated. The resulting photon may leave the object at many different angles with respect to the incident photon. No energy is transferred to the object. This phenomenon is known as coherent, elastic, or Rayleigh scattering. The incident x-ray photon can be considered to behave as a wave and the phenomenon of diffraction takes place (see below).

All of these properties of x-rays are used to measure various properties of materials. X-ray applications can be placed into three categories based on which of the above phenomena are exploited. These categories are x-ray radiography, x-ray fluorescence spectrometry, and x-ray diffraction.

X-rays were discovered by Wilhelm Roentgen in 1895. Soon after their discovery Roentgen used x-rays to image the bones in a human hand. The x-rays transmitted through the hand (phenomenon 1) were recorded on photographic film. The bones or other dense objects absorb x-rays more than do soft tissues or less dense materials (phenomenon 2). This method of imaging the internal structure of an object is known as x-ray radiography.

X-ray fluorescence spectrometry consists of the measurement of the incoherent scattering of x-rays (phenomenon 3 above). It is used primarily to determine the elemental composition of a sample.

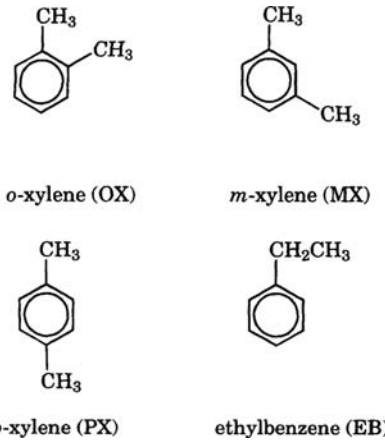
X-ray diffraction consists of the measurement of the coherent scattering of x-rays (phenomenon 4 above). X-ray diffraction is used to determine the identity of crystalline phases in a multiphase powder sample and the atomic and molecular structures of single crystals. It can also be used to determine structural details of polymers, fibers, thin films, and amorphous solids and to study stress, texture, and particle size. See also **X-Ray**; **X-Ray Analysis**; **X-Ray Imaging, Medical: Tomography and Radiography**; and **X-Ray Scan and Other Medical Imagery**.

X-RAY THICKNESS GAGE. See **Thickness Measurement and Gaging Systems**.

X-UNIT (or Xu). A unit used in expressing the wavelengths of x-rays or gamma-rays. It is about 10^{-11} centimeter of 10^{-3} Å. Accurately, $1\ \text{Xu} = 1.00202 \pm 0.00003 \times 10^{-3}$ Å.

XYLEM. The cells composing the woody tissue of higher plants are xylem cells. They have undergone extreme modification during their development, becoming greatly elongated and having much-thickened walls. Xylem tissue includes tracheids, vessels, fibers, and parenchyma.

XYLENES AND ETHYLBENZENE. Xylenes and ethylbenzene [CAS: 100-41-4] (EB) are C_8 aromatic isomers having the molecular formula C_8H_{10}. The xylenes consist of three isomers: *o*-xylene [CAS: 95-47-6] (OX), *m*-xylene CAS: 108-38-3] (MX), and *p*-xylene [CAS: 106-42-3] (PX). These differ in the positions of the two methyl groups on the benzene ring. The molecular structures are shown below.



Sources and Uses

The term *mixed xylenes* describes a mixture containing the three xylene isomers and usually EB. Commercial sources of mixed xylenes include catalytic reformate, pyrolysis gasoline, toluene disproportionation product, and coke-oven light oil. Ethylbenzene is present in all of these sources except toluene disproportionation product. Catalytic reformate is the product obtained from catalytic reforming processes.

Pyrolysis gasoline is a by-product of steam cracking of hydrocarbon feeds in ethylene. Coke over light oil is a by product of the manufacture of coke for the steel industry.

Properties

Because of their similar molecular structures, the three xylenes and EB exhibit many similar properties (see Table 1).

TABLE 1. PHYSICAL PROPERTIES FOR C_8 AROMATIC COMPOUNDS

Property	*p*-Xylene	*m*-Xylene	*o*-Xylene	Ethyl benzene
Molecular weight	106.167	106.167	106.167	106.167
Density at 25 °C, g/cm^3	0.8610	0.8642	0.8802	0.8671
Boiling point, °C	138.37	139.12	144.41	136.19
Freezing point, °C	13.263	−47.872	−25.182	−94.975
Refractive index at 25 °C	1.4958	1.4971	1.5054	1.4959
Surface tension, mN/m (= dyn/cm)	28.27	31.23	32.5	31.50
Dielectric constant at 25 °C	2.27	2.367	2.568	2.412
Dipole moment of liquid [a] Cm·	0	0.30	0.51	0.36
Critical properties:				
Critical density, mmol/cm^3	2.64	2.66	2.71	2.67
Critical volume, cm^3/mol	379.0	376.0	369.0	374.0
Critical pressure, MPa[b]	3.511	3.535	3.730	3.701

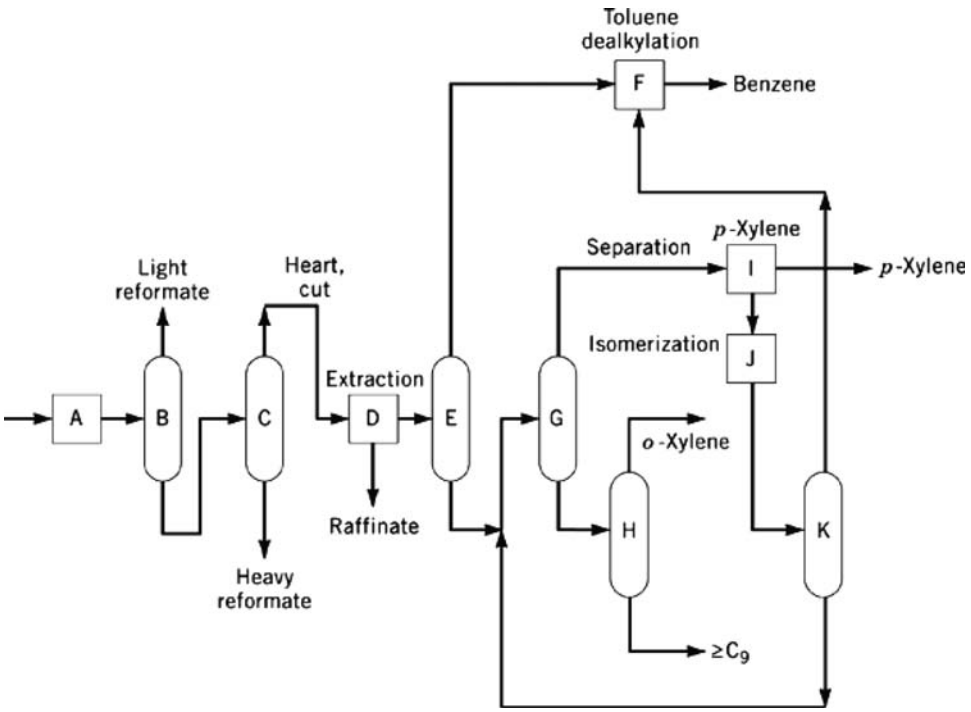

Fig. 1. General scheme for producing benzene, PX, and OX from catalytic reforming.

Chemical Properties

Chemical reactions that the xylenes participate in include (*1*) migration of the methyl groups, (*2*) reaction of the methyl groups, (*3*) reaction of the aromatic ring, and (*4*) complex formation.

Manufacture of Xylenes

The initial manufacture of mixed xylenes and the subsequent production of high purity PX and OX consists of a series of stages in which (*1*) the mixed xylenes are initially produced; (*2*) PX and/or OX are separated from the mixed xylenes stream; and (*3*) the PX- (and perhaps OX-) depleted xylene stream is isomerized back to an equilibrium mixture of xylenes and then recycled back to the separation step. These steps are discussed below.

Mixed Xylenes Production Via Reforming. Two principal methods for producing xylenes are catalytic reforming and toluene disproportionation. A general schematic for the production of PX and OX (along with benzene and toluene) via catalytic reforming is shown in Figure 1. In this example, a light fraction from a straight run petroleum fraction or from an isocracker is fed to a catalytic reformer, unit A. This is followed by heart-cutting and extraction in units B, C, and D. The mixed xylenes stream must then be processed further to produce high purity PX and/or OX. As discussed herein, high purity OX can be produced via distillation. However, because of the close boiling points of PX and MX, using distillation to produce high purity PX is impractical. Instead, other separation methods such as crystallization and adsorption are used.

Xylenes Production Via Toluene Transalkylation and Disproportionation. The toluene that is produced from processes such as catalytic reforming can be converted into xylenes via **transalkylation** and **disproportionation**. Toluene disproportionation is defined as the reaction of 2 mol of toluene to produce 1 mol of xylene and 1 mol of benzene. Toluene transalkylation is defined as the reaction of toluene with C_9 or higher aromatics to produce xylenes:

Other species that are also present in the feed, such as ethylbenzene and methylethylbenzenes will also undergo transalkylation reactions. These reactions tend to approach an equilibrium that depends on the operating conditions.

There are several commercial processes that produce xylenes via disproportionation or transalkylation. These include UOP's Tatoray and PX-Plus, ARCO's Xylenes Plus, and Mobil's MTDP and STDP.

The Tatoray process was originally developed by Toray and is currently licensed by UOP. In this process, toluene or a mixture of toluene and C_{9+} aromatics are reacted to form primarily xylenes and benzene. An equilibrium distribution of xylenes is produced.

Separation Processes for PX. There are essentially two methods that are currently used commercially to separate and produce high purity PX: (*1*) crystallization and (*2*) adsorption. A third method, a hybrid crystallization/adsorption process, has been successfully field-demonstrated.

Low temperature fractional crystallization was the first and for many years the only commercial technique for separating PX from mixed xylenes. PX has a much higher freezing point than the other xylene isomers. Thus, upon cooling, a pure solid phase of PX crystallizes first. Eventually, upon further cooling, a temperature is reached where solid crystals of another isomer also form. This is called the eutectic point. The solid PX crystals are typically separated from the mother liquor by filtration or centrifugation.

Adsorption represents the second and newer method for separating and producing high purity PX. In this process, adsorbents such as molecular sieves are used to produce high purity PX by preferentially removing PX from mixed xylene streams. Separation is accomplished by exploiting the differences in affinity of the adsorbent for PX, relative to the other C_8 isomers. The adsorbed PX is subsequently removed from the adsorbent by displacement with a desorbent.

In 1994, IFP and Chevron announced the development of a hybrid process that reportedly combines the best features of adsorption and crystallization. In this process, the adsorbent bed is used to initially produce PX of 90–95% purity. The PX product from the adsorption section is then further purified in a small single-stage crystallizer and the filtrate is recycled back to the adsorption section. It is reported that ultra-high (99.9+ %) purity PX can be produced easily and economically with this scheme.

MX Separation Process. The Mitsubishi Gas–Chemical Company (MGCC) has commercialized a process for separating and producing high purity MX. This process is based on the formation of a complex between MX and $HF–BF_3$. MX is the most basic xylene, and its complex with $HF–BF_3$ is the most stable.

MX of >99% purity can be obtained with the MGCC process with <1% MX left in the raffinate by phase separation of hydrocarbon layer from the complex-HF layer. The latter undergoes thermal decomposition, which liberates the components of the complex.

Xylene Isomerization. After separation of the preferred xylenes, i.e., PX or OX, using the adsorption or crystallization processes discussed herein, the remaining raffinate stream, which tends to be rich in MX,

is typically fed to a xylenes isomerization unit in order to further produce the preferred xylenes. Isomerization units are fixed-bed catalytic processes that are used to produce a close-to-equilibrium mixture of the xylenes. The catalysts are also designed to convert EB to either xylenes, benzene and lights, or benzene and diethylbenzene.

Health and Safety Factors

The xylene isomers are flammable liquids and should be stored in approved closed containers with appropriate labels and away from heat and open flames. The vapor can travel along the ground to an ignition source. In the event of fire, foam, carbon dioxide, and dry chemical are preferred extinguishers. The xylenes are mildly toxic. They are mild skin irritants, and skin protection and the cannister-type masks are recommended.

Uses

The majority of xylenes, which are mostly produced by catalytic reforming or petroleum fractions, are used in motor gasoline. The majority of the xylenes that are recovered for petrochemicals use are used to produce PX and OX. PX is the most important commercial isomer. Almost all of the PX is converted to terephthalic acid and dimethylterephthalate, and then to poly(ethylene terephthalate) for ultimate use in fibers, films, and resins.

Almost all of the OX that is recovered is used to produce phthalic anhydride, the phthalic anhydride is a basic building block for plasticizers used in flexible PVC resins, for polyester resins used in glass-reinforced plastics, and for alkyd resins used for surface coatings. Some of the mixed xylenes that are produced are used as solvents in the paints and coatings industry. However, this use has declined, particularly in the United States as environmental efforts to reduce hydrocarbon emissions into the air have increased.

XYLITOL. See **Sweeteners**.

X-Y RECORDER. An instrument used where it is desired to plot the relationship between two variables, $y = f(x)$, instead of plotting each variable separately as a function of time. An X–Y recorder closely resembles and functions like a single-pen recorder except that the chart (Y-axis) is moved in response to changes in a variable instead of at a uniform time rate. The chart may be driven by a separate servoactuated measuring element similar to that used in positioning the recorder pen, or by a self-synchronous motor in a remote-control system. In most applications of the X–Y recorder, a square-shaped graph sheet is used. Thus, the fullscale chart travel (Y-axis) is made equal to the fullscale pen travel (X-axis). The addition of a second servoactuated measuring element and recording pen to an X–Y recorder yields an $X–X_1–Y$, or an $X–Y–Y_1$ recorder in which the relationships among three associated variables can be plotted.

Y

YAG AND YIG. Synthetic yttrium aluminum and yttrium iron garnets, respectively. These materials were developed in the mid-1960s. They are pressed and sintered polycrystalline ceramics and are made by a solid-state reaction of Y_2O_3 with iron oxide [CAS: 1345-25-1] or aluminum oxide [CAS: 1344-28-1]. Garnets operate in microwave bandpass (filters) circulators and isolators in telephone, radar, and space-communication networks. The original electronic use led to the development of single-crystal yttrium aluminum garnets which approach the brilliance and hardness of diamond. Yttrium oxide is the base for neodymium-doped laser crystals. See also **Neodymium**; **Rare-Earth Elements and Metals**; and **Yttrium**.

YAGI ANTENNA. A type of directional antenna used on some types of radar and radio equipment consisting of an array of elemental, single-wire dipole antennas and reflectors.

YALOW, ROSALYN SUSSMAN (1921–). Rosalyn Yalow was an American medical physicist who helped develop the technique of radioimmunoassay (RIA), which detects very small quantities of biologically important substances in body fluids.

Rosalyn Sussman was born in New York City, the daughter of Simon Sussman and Clara Zipper. After showing early promise in chemistry, she was drawn to physics while studying at Hunter College (now part of the City University of New York), and in January 1939 attended the historic colloquium at which Enrico Fermi announced the discovery of nuclear fission. At that time, despite the widely publicized example of Marie Curie, opportunities for women to pursue a career in physics remained scarce. As Rosalyn's typing skills had already gained her part-time secretarial work at Columbia University before her graduation in January 1941, she was invited to continue in that capacity while attending graduate courses in physics through the "back door," as a university employee. However, she was soon offered a teaching assistantship in physics at the University of Illinois College of Engineering. On arrival there in September 1941, Rosalyn found herself the only female among 400 faculty members. (Aaron Yalow, who started the graduate program with her, became her husband in 1943; they have two children.) After gaining a doctorate in nuclear physics from Illinois in 1945, Rosalyn returned to New York to teach at Hunter College.

She became interested in the medical uses of radioisotopes, and in 1950 moved to a full-time post at the Radioisotope Service of the Veterans Administration Hospital in New York City. There, she collaborated with Solomon Berson in developing new medical techniques involving radioisotopes, including the study of iodine metabolism and the diagnosis of thyroid diseases. Their work on the metabolism of animal insulin's in the human body was particularly significant. They injected insulin labeled with radioactive iodine into human subjects, and measured the rate at which it disappeared. Contrary to expectations, elimination was slower in diabetics than in non-diabetics. Yalow and Berson argued (against strong opposition) that the diabetics had reacted to earlier injections of animal insulin by developing antibodies, which inhibited its absorption into the cells where sugars were metabolized. By 1959 they had developed and refined the highly sensitive technique of radioimmunoassay (RIA), which allowed them to demonstrate that radioactively tagged insulin molecules were indeed binding to specific sites on antibody molecules. RIA techniques soon became widely used for tracking small amounts of biologically significant substances in body fluids. See also **Radioisotopes**.

Berson died in 1972, but Yalow continued their work on RIA, and in 1977 she shared the Nobel Prize in Physiology or Medicine with Andrew Schally and Roger Guillemin. See also **Guillemin, Roger Charles Louis (1924-Present)**; and **Schally, Andrew Victor (1926-Present)**.

YANG, FRANKLIN CHEN-NING (1922–). Yang is an American physicist born in China. As a child, Chen Ning Yang read Benjamin Franklin's autobiography and was so inspired by Franklin's life that he took the name of "Franklin" as his first name. He received is Ph.D. from the University of Chicago, 1948. Chen-ning Yang was a member of the Institute for Advanced Study at Princeton, New Jersey from 1949 to 1955 and a professor of physics there from 1955 to 1965. In 1965 he was appointed Albert Einstein Professor of Physics of the State University of New York at Stony Brook and director of the Institute of Theoretical Physics at Stony Brook.

In 1957 Yang shared the Nobel Prize in Physics with American physicist Tsung-Dao Lee. They were the first scientists of Chinese birth to win a Nobel Prize. They were also among the youngest men ever to receive a Nobel award. They obtained the shortest time interval ever between a discovery and the award of the Nobel Prize. Their research refuting the law of parity, stated that at the subatomic level, nature does not distinguish between left-and right-handed configurations: if a nuclear reaction or decay occurs in nature, then so does its mirror image and with equal frequency. He is also known for his researches in statistical mechanics and particle physics.

In 1980, he was given the Rumford Medal of the American Academy of Arts and Sciences. Yang helped to advance science by his membership on the boards of Rockefeller University, the American Association for the Advancement of Science, the Salk Institute for Biological Studies in San Diego, and Ben-Gurion University in Israel.

YAPOCK. See **Marsupialia**.

YARDANG. A long, irregular, sharp-crested, undercut ridge between two round-bottom troughs, carved on a plateau or unsheltered plain in a desert region by wind erosion. Consisting of soft, but coherent deposits, such as clay-laden sand, it lies in the direction of the dominant wind.

YAW (Aircraft). This is the angular displacement about the normal axis of an aircraft. The normal axis of an airplane in horizontal flight is vertical. Intentional yaw is produced principally by the rubber. Yaw may be produced by the unsymmetric thrust forces when one engine quits

in a multi-engine design. Yaw is produced by the usual correction of providing aileron rolling moments to counter the torque of propeller-engine combinations.

The yawing moment may be expressed mathematically as follows:

$$N = qSCC_N$$

where C_N is the yawing moment coefficient, N is the yawing moment, S is the wing area, and C is the mean aerodynamic chord of the wing.

YAWS *(Frambesia; Pian).* A contagious disease caused by a spirochetal organism *Treponema pertenue* which is a close relative of the spirochete of syphilis. The disease is unevenly distributed throughout the tropics, being essentially a disease of hot, humid countries. It is not a venereal disease, and congenital transmission does not occur. Infection is by direct contact with an infective lesion.

After initially manifesting a small papule at the site of inoculation, the lesion enlarges to form a granulomatous papilloma, which usually ulcerates and contains infective treponemes. The lesion may regress and latent periods intervene, but relapses eventuate, infective lesions reappearing and lasting some 3 to 5 years.

Diagnosis is by microscopical examination of the lesion exudate. Humoral immunity develops soon after the initial infection and produces antibodies cross-reacting with other treponemes. They only partially protect the patient against reinfection.

It is to be noted that, as rural yaws dies out, men from the rural areas who visit cities are likely to acquire venereal syphilis. They then return to their villages with secondary syphilitic sores and from them infect children via the skin. The result is syphilis, not yaws, in the children.

Treatment of the disease relies, as in venereal syphilis, upon penicillin or tetracycline and mass campaigns using these drugs have had some success, but are hampered by the nomadic habits of many of the tribes in which the disease occurs.

R. C. V.

YAZOO STREAM. A stream (tributary) that flows parallel to the main stream for a considerable distance before joining it at a deferred junction. In particular, a stream forced to flow along the base of a natural levee formed by the main stream. Examples include the Yazoo River in western Mississippi, joining the Mississippi River at Vicksburg, Mississippi.

Y-CHROMOSOME. The Y chromosome, present in about half of the population, is essential for the propagation of the species but not life. It dictates the formation of testis and is required for spermatogenesis. It also participates in a variety of functions, such as bone development, tooth formation, and cell proliferation. Defects in Y-linked genes may result in sex reversal, male infertility, short stature and abnormal bone formation, and an increased risk of germ cell tumors. The Y chromosome — with the genes to make a man — has been sequenced, completed June 2003. Often regarded as a genetic wasteland, the sequence reveals that we may have underestimated its powers.

Function

Sex Determination. A major function of the Y chromosome is sex determination. It is executed by the *SRY* (sex-determining region Y) gene located in the Y-specific region immediately proximal to the PAR1 boundary. The ability of *SRY* to direct testis formation and subsequent male development is clearly demonstrated by the transgenic experiment in which XX mice carrying a *Sry* transgene developed as males. These sex-reversed males have testes and external male genitalia, and behave normally when caged with receptive females. However, they are sterile due to lack of germ cells. *SRY* is expressed briefly in the male genital ridge during embryogenesis, and is thought to trigger differentiation of the Sertoli cell lineage in the testis. In its absence, the same cell would become a follicle cell in the ovary.

The human SRY protein consists of 204–amino acid residues. Apart from a central high mobility group (HMG) box of about 78 amino acids, the sequence of SRY is poorly conserved among species. The protein binds to DNA through the HMG box in a sequence-specific fashion, and causes sharp bends in the DNA helix to facilitate the assembly of transcriptional machinery. The downstream targets of SRY have not been identified, and potential targets include genes that are upregulated during early testicular development.

Sex reversal can be caused by a misplaced or nonfunctional *SRY* gene. The human *SRY* gene, located within 7 kb of the PAR1 boundary, is prone to be translocated to the X chromosome in an aberrant X–Y crossing over. See also **X-Chromosome**. Indeed, one out of 20,000 males has an XX karyotype, and 80% of them contain a translocated *SRY* gene. These XX males have grossly normal appearance, except that they have small testes with little or no germ cells and are infertile. An individual who has inherited the Y chromosome lacking the *SRY* gene will become an XY female. Sex reversal can also be caused by a defective *SRY* gene due to missense or nonsense mutations in the HMG box. Such mutations have been found in more than 20% of XY females with pure gonadal dysgenesis. These XY females have fibrous streak gonads devoid of follicles and germ cells, and about one-third of them will develop germ cell tumors such as gonadoblastoma and dysgerminoma. On the basis of Y chromosome segments retained in these XY females, a gonadoblastoma gene *GBY* was mapped to interval 3G-4B. Among the genes mapped to that region, *TSPY* (testis-specific protein, Y) is expressed in gonadoblastoma and is considered a strong candidate for *GBY*.

Spermatogenesis. Many genes on the Y chromosome have either testis-specific expression or testis-specific transcripts, implicating a role in spermatogenesis). Indeed, 10 to 15% of azoospermic males and a smaller percentage of severely oligospermic men have microdeletions on their Y chromosomes. Most of the deletions fall in three nonoverlapping regions on the long arm, designated as *AZFa*, *AZFb*, and *AZFc*. *AZFa* contains at least two functional genes, *USP9Y* (ubiquitin specific protease 9, Y, also known as *DFFRY*) and *DBY* (dead box, Y) that encodes a putative RNA helicase. Deletion of both genes results in Sertoli-cell-only syndrome, whereas defects in the *USP9Y* gene alone cause spermatogenic arrest or hypospermatogenesis. Both *USP9Y* and *DBY* are ubiquitously expressed and have X-homologs that apparently cannot compensate for their defects.

Among the genes mapped to the *AZFb* region in interval 5Q-6 C, *RBMY* (RNA-binding motif, Y, also known as *YRRM*, *RBM*) was the first one isolated. The *RBMY* gene family consists of approximately 30 members distributed on both arms of the Y chromosome. However, the functional copies appear to be clustered within *AZFb*. *RBMY* encodes germ-cell specific RNA-binding proteins that are present in the nuclei of spermatogonia, spermatocytes, and round spermatids. It appears to play a role in pre-mRNA splicing. Male mice lacking most of their *RBMY* genes remain fertile despite a significant increase in abnormal sperm in their semen.

AZFc at distal interval six is the most frequently deleted region. Patients with *AZFc* deletion have variable phenotypes, ranging from Sertoli-cell-only syndrome to hypospermatogenesis. Some of these patients have fathered children either naturally or with assistance. Within the *AZFc* region is the *DAZ* family which encodes another germ-cell specific RNA-binding protein. *DAZ* homologous sequences are present only on the Y chromosomes of great apes and old world monkeys, whereas an autosomal *DAZ*-like gene, *DAZL1* (also known as *DAZLA*, *DAZH*, *DAZL*), is present in all mammals. *DAZ* and *DAZL1* are homologous to a *Drosophila* male infertility gene *boule*, and *DAZL1* knockout mice are sterile, supporting a role for these genes in spermatogenesis. The DAZ and DAZL1 proteins are present mainly in the cytoplasm, and the association of DAZL1 with actively translating polyribosomes suggests a role in germ-cell specific regulation of mRNA translation. In addition to *DAZ*, *CDY* and *BPY2* (basic protein, Y2) within *AZFc* also show testis-specific expression.

Stature. The stature of an individual is controlled by two loci on the Y chromosome. The *SHOX* (also known as *PHOG*) gene within PAR1 encodes a protein with a homeobox domain and is expressed at highest levels in osteogenic cells. Deletions or point mutations of *SHOX* are found in a small percentage of individuals with idiopathic short stature, and some patients with Leri-Weill dyschondrosteosis who have Madelung deformity of the forearm in addition to short stature. Homozygous mutations in *SHOX* result in the more severe Langer mesomelic dwarfism. Haploid insufficiency of *SHOX* may also be responsible for the short stature of Turner syndrome patients. Another locus controlling

stature has been mapped to interval 4B–5G, but the gene has not been identified.

H-Y Antigens. Proteins encoded by the Y chromosome are absent in females. Some of them contain antigenic epitopes which elicit immune response and cause graft rejection following sex-mismatched organ or bone marrow transplantation. A few such male specific H-Y antigens have been identified, and they are encoded by *SMCY* (selected mouse cDNA, Y), *UTY* (ubiquitous TPR motif, Y), and *USP9Y*.

Other Functions. In addition to genes associated with some phenotypes, the human Y chromosome contains genes that encode receptors for cytokines and growth factors, transcription and translation factors, cell surface antigens, enzymes involved in signal transduction, melatonin synthesis and energy metabolism, and genes that code no proteins. It is therefore involved in a wide variety of biological processes and cellular functions.

Y-CONNECTION. Three-phase ac equipment is wound with three wires whose currents differ 120° electrically in phase. The windings can be connected either in Y or delta. In balanced electrical condition, voltages and currents are the same in all coils. In the Y-connections one end of all three coils is connected in a common joint, and leads from each of the other ends constitute the three-phase line. The Y-connection is preferred for alternators because of the usefulness of the neutral point, and because the line voltage is $\sqrt{3}$ times the phase voltage. The ability to bring out a neutral point and ground it either through resistance or reactance, is advantageous because it aids in working out protection and selectivity of control of parallel alternators.

YEAST CELLS. See **Ascomycetes (Sac Fungi; Fungi)**.

YEASTS AND MOLDS. These are very important plant organisms that make both positive and negative contributions to mammalian life processes. Their plus and minus values are particularly noted in connection with the production and storage of food products.

Taxonomy. Plants that lack true roots, stems, or leaves, and that are without highly-organized conducting systems are called *simple plants*, and they make up the phylum *Thallophyta*. The two subdivisions of *Thallophyta* are *algae* and *fungi*. Algae have chlorophyll; fungi do not. Fungi utilize carbohydrates that are synthesized by green plants. Fungi are classified as *parasites* or *saprophytes*, the latter obtaining food from nonliving organic material. The science of fungi is *mycology*. See also **Fungus**.

The fungi include: *Slime molds* (*Myxomycetes*); *algal fungi* (*Phycomycetes*); *sac fungi* (*Ascomycetes*); and *club fungi* (*Basidiomycetes*); among others. The yeasts and most of the molds with which food products are associated in some way are of the *Ascomycetes* variety.

The varied interface between the *Ascomycetes* and foods ranges from their very negative, parasitic habit on certain crops (exemplified by Chestnut blight fungus; or ergot on grains) and their causative involvement in certain foodborne diseases to their positive use in connection with the production (notably by fermentation) of major food products, such as bread and wine.

The term *yeast* is used to describe a relatively small number of *Ascomycetes* fungi (a few hundred — Lodder et al. (1970) classified 349 fermentative species, of which relatively few are used industrially), as compared with the vast number of other fungi (several thousand) that have been identified.

The term *mold* does not have a clear cut mycological definition. While the yeasts have a preponderantly positive value in food production and utilization, the molds make some positive contributions (some cheeses, etc.), but they participate in many more negative ways (leaf molds on plants; blue-green molds on fruits; machinery mold; causes of some foodborne diseases; etc.). Some authorities identify all or most mold as *saprophytes*, as previously defined. This identification, however, is not fully satisfactory in terms of the present loose ways in which the word mold is used in the professional literature. Molds do play an important role in the *biodegradation* of unwanted substances.

Yeasts

The importance of the economically useful yeasts can be attributed to two main factors: (1) *fermentation* — the transformation of simple sugars and other organic chemicals to other, more desirable chemicals; and (2) *respiratory* (*oxidative*) *metabolism* — the great capacity of some yeasts for a protein synthesis during growth in richly aerated media containing a wide variety of carbonaceous and nitrogenous nutrients. Thus, yeasts serve in many ways: (1) As living cells, they are biocatalysts in the production of bread, wine, beer, distilled beverages, among other important food products. (2) As dried, nonfermentative whole cells or hydrolyzed cell matter, yeasts contribute nutrition and flavor to human diets and animal rations. (3) As producers of vitamins and other biochemicals, yeasts are a rich source of enzymes, coenzymes, nucleic acids, nucleotides, sterols, and metabolic intermediates. See also **Coenzymes**; **Enzyme**; and **Enzyme Preparations**. (4) As a versatile biochemical tool, yeasts aid research studies in nutrition, enzymology, and molecular biology.

Background. It is estimated that the arts of making wine, leavened bread, and beer were practiced more than 4000 years ago. The phenomena for producing these foods were attributed to "yeast" at an early age. In many languages, the word for yeast describes the visible effects of fermentation, as observed in the expansion of bread dough and the accumulation of froth or barm on the surface of fermenting juices and mashes. Historically, it has been reported that yeast cells were first seen in a droplet of beer mounted on a slide in a crude microscope used by van Leeuwenhoek in 1680. He found globular bodies, but was not aware that they were living forms. For nearly two centuries the theory of spontaneous generation dominated thought and research on the causes of fermentation and disease. In 1818, Erxleben described beer yeast as a living vegetable matter responsible for fermentation. In the following twenty years, yeasts were shown to reproduce by budding and, in 1837, Meyen named yeast *Saccharomyces*, or "sugar fungus." By 1839, Schwann observed "endospores" in yeast cells, later named ascospores by Reess. As early as 1857, Pasteur proved the biological nature of fermentation and later, in 1876, Pasteur demonstrated that yeast can shift its metabolism from a fermentative to an oxidative pathway when subjected to aeration. This shift, then named the Pasteur effect, is especially characteristic of bakers' yeast (*Saccharomyces cerevisiae*) and is applied in the large-scale production of yeasts.

Botanically, yeasts form a heterogeneous group of saprophytic forms of life occurring naturally on the surface of fruits, in honey, exudates of trees, and in soil. They are disseminated by airborne dusts, insects, and animals. Typically, industrial yeasts are generally oval, microscopic, unicellular organisms. In addition to lacking chlorophyll, they also lack locomotion. They reproduce vegetatively by budding and sexually by spore formation (ascospores) within the mother cell or ascus. These properties place them in the family *Endomycetacea* of the class

Ascomycetes, as previously mentioned. Among the most important industrial yeasts are:

Saccharomyces cerevisiae (alcoholic beverages and bread)
S. cerevisiae var. *ellipsoideus*; *S. bayanus*; and *S. beticus* (wines)
S. uvarium (formerly called *S. carlsbergensis*) (beer, ale, etc.)
Kluyveromyces fragilis (formerly called *S. fragilis*) (whey disposal)

Food and feed yeast production employ several molds in the family *Cryptococcaceae: Candida utilis* , *C. tropicalis*, and *C. japonica* , which are cultivated on plant wastes (wood sugars, molasses, stillage), and C. lipolytica, which converts hydrocarbons to yeast protein.

Properties of Yeasts. The cell structure of *S. cerevisiae*, as observed in the optical microscope, reveals a rigid cell wall, a colorless, granular cytoplasm, and one or more vacuoles. Dimensions of a typical bakers' yeast are about 4 to 6 by 7 to 10 micrometers. Electron microscopy of ultrathin sections of a yeast cell show the microstructures, including: birth and bud scars on the cell wall, plasmalemma (cytoplasmic membrane), nucleus, mitochondria, vacuoles, fat globules, cytoplasmic matrix and volution or polyphosphate bodies. The cell walls of bakers' yeast contain 30–35% glucan (yeast cellulose), 30% mannan (yeast gum), which is bound to protein (about 7%), 1–2% chitin, 8–13% lipid material, plus inorganic components, largely phosphates.

Gross chemical composition of compressed bakers' yeast is approximately 70% moisture. The dry matter is made up of 55% protein ($N \times 6.25$), 6% ash, 1.5% fat, and the remainder mostly polysaccharides, including about 15% glycogen and 8% trehalose.

Food yeast, molasses-grown, is dried to about 5% moisture and has the same chemical composition as bakers' yeast. In terms of micrograms per gram of yeast, the vitamin content is: 165 thiamine; 100 riboflavin; 590 niacin; 20 pyridoxine; 13 folacin; 100 pantothenic acid; 0.6 biotin; 160 para-aminobenzoic acid; 2710 choline; and 3000 inositol. Yeast crude protein contains 80% amino acids; 12% nucleic acids; and 8% ammonia. The latter components lower the true protein content to 40% of the dry cell weight.

Yeast protein is easily digested (87%) and provides amino acids essential to human nutrition. Most commercial yeasts show the following pattern of amino acids, among others, as percent of protein: 8.2% lysine; 5.5% valine; 7.9% leucine; 2.5% methionine; 4.5% phenylalanine; 1.2% tryptophan; 1.6% cystine; 4% histidine; 5% tyrosine; and 5% arginine. The usual therapeutic dose of dried yeast is 40 grams/day, which supplies significant daily needs of thiamine, riboflavin, niacin, pyridoxine, and general protein.

The ash content of food yeasts ranges from 6 to 8% (dry basis), consisting mainly of calcium, phosphorus, and potassium. Contained in quantities of less than 1% are magnesium, sulfur, and sodium. At the microgram level are included iron, copper, lead, manganese, and iodine.

Triglycerides, lecithin, and ergosterol are the main constituents of yeast lipid (fat). Oleic and palmitic acids predominate in yeast fat. These resemble the composition of common vegetable fats. Ergosterol, the precursor of calciferol (vitamin D_2) varies from 1 to 3% of yeast dry matter.

Metabolic Activity. This is generally associated with the familiar alcoholic fermentation in which theoretically 100 parts of glucose are converted to 51.1 parts of ethyl alcohol (ethanol), 48.9 parts of carbon dioxide (CO_2), and heat. In addition, however, the anaerobic reaction also yields minor byproducts in small amounts — mainly glycerol, succinic acid, higher alcohols (fusel oil), 2,3-butanediol, and traces of acetaldehyde, acetic acid, and lactic acid. Fusel oil is a mixture of alcohols, including *n*-propyl, *n*-butyl, isobutyl, amyl, and isoamyl alcohols.

Respiratory activity of oxidative dissimilation is characteristic of many species of yeasts. During aerobic growth, sugar is oxidized to carbon dioxide and water, with release of large amounts of energy (about 680 kcal when complete oxidation occurs). Aerobiosis produces a variety of byproducts, some in unusually high concentration, such as acetic acid, succinic acid, zymonic acid, polyhydric alcohols (glycerol, erythritol, etc), extracellular lipids, carotenoid pigments in shades of red and yellow, black pigment (melanin), and capsular polysaccharides (phosphomannan).

Production. Well over 85,000 tons (76,500 metric tons) of yeast dry matter are produced in the United States alone each year. About 75% of this is in the form of bakers' yeast, the remaining 25% represents about equal amounts of food yeast and feed yeast. This production issues from four types of manufacture: (1) Bakers' yeast is grown batchwise in aerated molasses solutions. (2) *Candida utilis* is obtained from wood pulp mill spent liquid. (3) *K. fragilis* is grown batchwise in cottage cheese whey. (4) Dried yeast is recovered as spent beer yeast. Worldwide production of all types of food and feed yeast is estimated at more than 450,000 dry tons (405,000 metric tons) per year.

The process for growing bakers' yeast is a model system for the propagation of microorganisms. The process commences with a laboratory culture of a pure strain of *S. cerevisiae*. Seed yeast is developed in successively larger volumes of nutrient solutions, beginning with a Pasteur flask and ending in a fermenting tank containing as much as 40,000 gallons (1514 hectoliters) of sterilized and diluted molasses maintained at 30 °C. During the highly aerated growth period, minerals are added, pH is adjusted to 4.5, and diluted molasses is continuously fed in proportion to the increase in cell mass. Under ideal conditions, yeast cells may double in number every 2.5 hours, converting more than half (56.7%) of the sugar supplied to cell components. Biosynthesis of cell matter requires an equal amount of oxygen. To produce 100 weight units of yeast dry matter with 50% protein content requires about 400 weight units of molasses, 25 weight units of aqua ammonia, 15 weight units of ammonium sulfate, and 7 weight units of monobasic ammonium phosphate. For each 100 pounds of dry yeast, 75,000 cubic feet of air are required; for 100 kilograms of dry yeast, 4,683 cubic meters of air are needed.

Fermentation Processes. The biochemistry of alcoholic fermentation involves a series of internal enzyme-mediated oxidation-reduction reactions in which glucose is degraded via the Embden-Meyerhof-Parnas pathway. See also **Carbohydrates**; and **Glycolysis**.

Some typical reactions performed by yeasts are listed in the Table 1.

Post-Processing Spoilage of Food by Yeasts. Microbiological spoilage of food is a competitive process occurring among yeasts, bacteria, and molds. Yeasts normally play a small role in spoilage, because they constitute only a small portion of the initial population, because they grow slowly in comparison with most bacteria, and because their growth may be limited by metabolic substances produced by bacteria. Evidence does not show food poisoning as caused by the presence of spoilage yeasts in foods. The byproducts of metabolism are not considered toxic and, while there are a few yeasts that may be considered pathogenic, they are not known to be responsible for foodborne infections or intoxications (Walker, 1977; Peppler, 1977). The metabolism of yeasts can result in the development of unnatural flavors and odors and changes in pH because of the utilization of organic acids important in fermented foods. Many yeasts are capable of utilizing lactic, acetic, and citric acids, which are essential for production of flavor and for preservation of some foods. Decreased concentration of these acids causes an increased pH and produces conditions that favor growth of spoilage bacteria. Normally, several factors interact to establish conditions that favor growth and subsequent spoilage of foods by yeasts. Examples of food spoilage by yeasts are given in the lower half of Table 1.

Although yeasts are abundant in nature, notably on leaves and in the soil, they do not compete with bacteria and molds as sources of major problems. But, in assessing the potential for spoilage by yeasts, one must consider those factors which are favorable or unfavorable to the growth and multiplication of yeast populations. Availability of oxygen is important. No yeast is known that can grow under strictly anaerobic conditions; thus, all require oxygen to be present in some proportion. Temperature is also an important factor. Yeasts are not heat resistant in the sense that bacterial endospores are heat resistant. Most yeasts cannot withstand temperatures above 65–70 °C. The majority of yeast species have an optimum temperature for growth between 20 and 30 °C. Even though yeasts are very resistant to low temperatures and can survive frozen storage, they normally are not a major problem in spoilage of frozen or refrigerated foods. In refrigerated foods, psychrotrophic bacteria rapidly outnumber the yeasts, the latter constituting a minor part of the initial population. However, where antibiotics or ionizing radiation have been used to reduce or inhibit bacterial growth, then yeast population may predominate. If the definition of a *psychrophilic* organism is one that has an optimum temperature below 20 °C, then there are a number of strains of psychrophilic yeasts.

The survival and growth of all organisms is dependent on the presence of some water in the environment. Yeasts generally require more moisture

TABLE 1. REACTIONS IN WHICH YEASTS PARTICIPATE[1]

Type of Reaction	Number of Known Reactions	Examples of Reactions
Reduction	156	Diacetyl to acetoin (in beer); cinnamic aldehyde to cinnamic alcohol.
Decarboxylation	21	Malic acid to lactic acid (in wines); amino acids to amines (histamine and tyramine accumulate in soft cheeses because of surface growth of *Torulopsis candida* and *Debaryomyces kloeckera*).
Deamination	17	Examples of deamination and decarboxylation include conversion of amino acids to fusel oil (leucine to isoamyl alcohol, isoleucine to amyl alcohol, and phenylalanine to phenyl ethanol). Fusel oil formation is a normal function of all yeast fermentations (in alcoholic beverages, levels range from trace to 2200 parts per million). Deamination: Glutamic acid to gamma-OH-butyric acid (*S. cerevisiae*).
Oxidation	14	Acids, alcohols, sugars, hydrocarbons. Also stepwise: alcohol to aldehyde or acid (sake yeast).
Esterification	10	Ethyl acetate (*Hansenula anomala*).
Condensation	9	Acetaldehyde to acetoin; acetaldehyde to pyruvic acid to alpha-acetolactic acid.
Hydrolysis	5	Starch hydrolysis: By *Endomycopsis fibuligera*; artichoke starch (inulin) by *Kluyveromyces fragilis*.
Amination	1	

Examples of Lesser-known Properties and Characteristics of Yeasts

Type of Reaction	Yeasts Involved	Examples
Lipolysis	*Candida lipolytica; C. rugosa; Torulopsis sphaerica*	Mainly in butter, margarine, and cheese.
Proteolysis	*C. lipolytica; T. sphaerica*	Especially on soft cheese surfaces.
Pectinolysis	*Saccharomyces kluyveri; Kluyveromyces fragilis; Hansenula anomala*	Softening of olives and cherries in brines, followed by formation of gas pockets in fruit. Strains of wine yeasts contain polygalacturonases which, during fermentation of grape juice, participate in the solubilization of pectin.
Acid formation	Species of Brettanomyces, Hansenula, Pichia, Saccharomyces	As a contaminant in wines, Brettanomyces spp. Forms a higher concentration of volatile acids (also isobutyric and isovaleric acids) than *S. cerevisiae*. Pichia species and other yeasts are responsible for acetic acid production in brines of domestic green olives; not lactobacilli, as assumed for years (Vaughn et al., 1976).
Pigmentation	*Rhodotorula glutinis*. Sporobolomyces spp.	Carotenoids (pink, red); *Rhodotorula glutinis causes* pink sauerkraut and discolors the surface of high-moisture cheeses.
Esterification	Species of Hansenula, Kluyveromyces, Brettanomyces	Ethyl acetate and ethyl lactate in cottage cheese and shredded Mozzarella cheese. See also **Milk and Dairy Products**.
Turbidity formation	In wine: *Saccharomyces bailii, S. chevalieri*, Brettanomyces spp. In beer: *S. diastaticus, S. bayanus*	In soft drinks; in wine: *S. bailli*, *S. chevalieri*; in beer: *S. diastaticus*, *S. bayannus*.

[1]Based, in part, upon Peppler et al. (1977).

for growth than molds, but less than bacteria. Systems containing high concentrations of sugar or salt have low a_w values or high osmotic pressure (Walker, 1977). Organisms growing in such systems are usually referred to as being *osmophilic*. A number of investigators have not been able to find any yeast that is clearly osmophilic. Windisch (1969) suggested the term osmotolerant to describe some yeasts. It is important to note that yeasts that normally will not grow in a high-sugar environment may appear, if the substance has been exposed to the air sufficiently to absorb water and dilute spots or edges of the material, thus favoring yeast growth. Species such as *Saccharomyces rouxii*, *S. rouxii* var. *polymorphus*, and *S. mellis* (Lodder, 1952) are capable of spoiling high-sugar foods, such as honey, maple sugar, sugar cane syrups, molasses, fruit syrups, candy, crystallized fruits, jams, jellies, and dried fruits. It is not uncommon for dried figs and prunes to be covered with a white coating of yeast during storage. The foods have a typical fermented odor and may contain gas pockets. This coating normally is a mixture of sugar and yeasts, with the principal yeast being *Schizosaccharomyces octosporus*.

Molds

The most critical factor in mold growth is the availability of sufficient moisture. Molds are widely distributed throughout nature. Chemicals for the destruction of molds, including those in the soil, are mentioned in the entry on **Antimicrobial Agents (Foods)**. In addition to food spoilage, various molds can be destructive of various materials, notably of substances prepared from animal skins, such as leather, book covers, shoes, and materials prepared from vegetable substances, such as paper and wood products. In warm, humid areas, mold (mildew) grows on wooden structures, including painted surfaces unless these have been chemically treated. In the case of foods, molds cause innumerable problems during the full cycle of food production.

Storage temperature of food is less important than the presence of moisture, since fungi can grow and produce toxins over a wider span of temperatures than can any other microorganisms. Most species are able to grow at an a_w of 0.8 to 0.88; while xerophilic types can grow at an a_w of 0.65 to 0.75. A relative humidity of from 70 to 90% establishes suitable moisture equilibrium for initiation of mold

growth and toxin formation in numerous food products. See also **Activity Coefficient**.

Unfortunately for the would-be consumer of food, fungal contamination is not always immediately apparent and thus may not seem to be cause either for the rejection of food by humans or for the rejection of feedstuffs by livestock. Concentrations of mold organisms are not always easy to see or to smell. Further, the relative stability of most mycotoxins to heat precludes the use of cooking as a detoxifying procedure. Among the most aggressive of the molds are species of *Candida, Aspergillus, Rhizopus*, and *Mucor*. Several of the fungi are not pathogenic to healthy humans, but may be virulent pathogens in debilitated persons, or those treated with broad-spectrum antibacterial drugs, or immunosuppressive measures. An example of this type of organism is *Cryptococcus neoformans* (Davis, 1973). Many of the fungi produce disease through infection rather than through mycotoxin production, but this usually requires predisposing factors.

Milner and Geddes pointed out in 1946 that the aflatoxigenic organism *Aspergillus flavus* is a common soil fungus throughout the world, and aflatoxin-contaminated food has been noted in many countries for a number of years (Wogan, 1966). Crops, such as groundnuts (peanuts), in intimate contact with soils, are likely to contact the necessary mold inoculum for aflatoxin production, resulting in toxin formation upon storage in air.

Several investigators have shown that toxic strains of *Fusarium, Cladosporium, Penicillium*, and *Mucor* can sporulate and grow at temperatures well below 0 °C. It also has been shown that toxin formation can be associated with overwintering of grain in the field. In some varieties of barley, such as Siri and Mala, the incidence of *Aspergillus* and *Penicillium* species is related solely to temperature and moisture storage conditions and is not correlated to the percentage of unripe grains. Low humidities tend to predispose hosts to invasion by molds by causing them to lose turgor. Mold is the cause of serious problems in connection with rice. The predominant molds present in wild rice during fermentation curing are *Mucor*, aflatoxigenic and nontoxigenic *Aspergillus, Penicillium*, and *Rhizopus* species. Most of the B_1 aflatoxin is in the hulls and the level of the toxin can be reduced by parching, which serves to reduce, but not fully destroy molds.

Contamination of soybeans with *Aspergillus flavus* is found in approximately 50% of commercial samples. Fortunately, the incidence of aflatoxin from this route is quite low. Moisture at the time of maturity, development of the seed in a closed pod, and binding of zinc by phytic acid are suggested as reasons for resistance of soybeans to aflatoxin production.

The most active sugar contaminants are molds, particularly *Aspergillus*. Penicillium growth on cheddar cheese results in a pH gradient, increasing to a pH of 8 at the surface. Mycotoxins diffuse through foods and are not removed when the surface molds are removed. Therefore, molds of unknown variety or origin should not be ingested. On the other hand, many of the common molds found as contaminants of Western foods are used in Asian fermented foods and beverages, principally as sources of flavor.

Degradation of Aflatoxin. Numerous researchers have investigated a variety of chemical and physical means for degrading aflatoxin. These include the use of irradiation, heat, acids and bases, oxidizing agents, bisulfite, and biological agents. The practical application of ultraviolet radiation to date has not proved successful. Aflatoxin is quite heat stable. Numerous investigators have concluded that although heat can degrade aflatoxins, it is not an effective and economically feasible means for inactivating these toxins when present in foods or feeds.

Among oxidizers used have been sodium hypochlorite, potassium permanganate, and hydrogen peroxide. Bisulfite is commonly used in the wet milling of corn (maize) and in processing wines, fruit juices, jams, and dried fruits.

Machinery Mold. This mold generally refers to the buildup of the organism *Geotrichum candidum* on food-contact factory equipment in processing plants. The term *dairy mold* is used in the processing of milk to identify this mold.

Since passage of the original Federal Food and Drugs Act of 1906 (United States), the presence of machinery mold in any food processing plant is a violation of regulations. Antimicrobial agents have made it possible to keep machinery clear of this mold. The mold can be particularly bothersome in tomato and pineapple processing plants. See also **Antimicrobial Agents (Foods)**.

YELLOW FEVER. An endemic or epidemic disease caused by the *yellow fever virus*, which is a togavirus (Group B arbovirus, or flavovirus). Humans are the usual reservoir, but, in jungle areas, nonhuman primates may also carry the virus. The vector for transmitting the virus between humans is the mosquito, *Aedes aegypti*. Transmission between nonhuman primates is by an arthropod vector. Twelve days after biting an infected patient, the mosquito is then able to infect a nonimmune person. During the 18th and 19th Centuries, yellow fever was seen in North America and Europe, having been transmitted by mosquitoes breeding in the open water tanks of sailing vessels. In recent years, the mosquito has been essentially eliminated in the Caribbean, the southern United States, and Central America. Because the disease remains endemic in South America and sub-Saharan Africa, persons traveling to and through these areas require immunization with an effective yellow fever virus vaccine.

The U.S. Centers for Disease Control (Atlanta, Georgia) report that the last indigenous case of yellow fever was seen in the United States in 1911 and the last imported case was in 1924. However, devastating epidemics have occurred in Ethiopia (1960, 1962) and in Senegal (1965) causing many thousands of deaths.

Yellow fever is characterized by severe, fulminant hepatitis, accompanied by nephritis and hemorrhages. The incubation period is from 3 to 6 days. The symptoms in most cases are mild and consist of fever, headache, and perhaps jaundice. A severe case, however, is characterized by a sudden onset, acute prostration, fever, slow pulse rate, generalized aches and pains, and jaundice. The kidneys are particularly involved and large amounts of albumin in the urine is a feature. Vomiting may be described as uncontrollable. The tongue becomes bright red and the conjunctivae congested. Facial edema and flushing occur — to be replaced by a dusky pallor. The gums become swollen and there is a marked bleeding tendency with black vomit, melena, and ecchymoses. If the disease is left untreated, failure of the kidneys, with complete suppression of their function, or excessive

bleeding from the gastrointestinal tract, usually occurs, and in such cases the mortality rate may be as high as 60%. Death, when it occurs, comes usually within 6 to 7 days and rarely after ten days.

Treatment is essentially supportive. Prevention is by mosquito eradication and administration of vaccine. The 17D vaccine strain used causes few complications. In some recipients (about 5%), headache, myalgia, and low-grade fever may persist for 5–10 days after inoculation. Encephalitis is a very rare complication. It is estimated that over 34 million doses of 17D vaccine had been administered in the United States prior to 1980, as a result of which only two cases of encephalitis were reported. The French Dakar strain of vaccine is much less favored by most physicians because records indicate that it may cause meningoencephalitis in about 0.5% of the inoculations. Contraindications of yellow fever vaccine are hypersensitivity to eggs and pregnancy.

YELLOWFIN MENHADEN. See **Menhaden**.

YELLOWFIN TUNA. See **Tunas**.

YELLOW-GREEN ALGAE. A group of algae corresponding to the division *Chrysophyta*, the greenish-yellow to golden-brown color derived from chromatophores of that range of pigmentation. These algae usually have a cell wall composed of overlapping halves.

YELLOW-JACKET *(Insecta, Hymenoptera).* A small black and yellow wasp that builds its nest of paper, either in a hole in the ground or under some object near the ground. The use of partly decayed wood in making the paper gives these nests a brownish color. Several species are known. The insect is found in Europe, Asia, and North America. It is an aggressive scavenger and possesses a vicious sting.

YERSIN, ALEXANDRE (1863–1943). Alexandre Yersin was a Swiss-born French bacteriologist who characterized the diphtheria exotoxin, identified the plague bacillus, and developed anti-plague serum.

There is a long-standing legend that Yersin first met Louis Pasteur and his associate Émile Roux as a patient, receiving the newly developed anti-rabies treatment at Pasteur's clinic after suffering a cut while performing an autopsy on a rabies victim. Unfortunately this story cannot be confirmed either by Pasteur's records or by Yersin's own letters. The more likely story is that after meeting Roux in 1886, while a medical student and working at the Hôpital Hôtel-Dieu, Yersin began to make regular visits to Pasteur's clinic, eventually assisting in the anti-rabies treatments there. Yersin would develop a close working relationship with Roux, first as laboratory assistant in Roux's experiments with tuberculosis, later in their research on the diphtheria bacillus, and as Roux's demonstrator in the first course in microbiology techniques taught at the Institut Pasteur. See also **Pasteur, Louis (1822–1895)**; **Rabies**; and **Roux, Pierre Paul Émile (1853–1933)**.

Yersin's experiments with tuberculosis in Roux's laboratory led to his doctoral thesis (defended in 1888) in which he described an experimental animal model of tuberculosis. But Yersin was more interested in diphtheria, which he encountered with sad frequency during his placement at the Hôpital des Enfants-Malades. The bacteria could only be cultured from the pseudo-membranes that characteristically formed in the throats of diphtheria patients, though the disease had obvious effects in the blood and tissues, and was often accompanied by paralysis. Yersin and Roux speculated, and later demonstrated, the presence of a bacterially produced toxin with generalized effects. Using the toxin they reproduced the disease symptoms in bacteria-free trials. This was the first demonstration of a bacterial exotoxin. See also **Bacteriology (The History)**; and **Tuberculosis**.

Struck by a desire to travel, Yersin left Paris in 1890 to travel as ship's doctor with the merchant navy. He worked on the Manila–Saigon route, and soon formed a strong attachment to the land and people of Annam (now part of Vietnam). He spent his time on land exploring and mapping, eventually taking a leave to explore the thickly forested mountain interior. He was the first to map the plain of Lang Bian, where eventually was established the colonial resort town of Dalat.

In 1894 the bubonic plague had a death-hold on Hong Kong, and Yersin was sent by the French government to apply his expertise. At first he was refused access to laboratory facilities and autopsies, as the Japanese bacteriologist Shibasaburo Kitasato had arrived days earlier and had secured priority to the limited facilities. Yersin gained access to bodies of plague victims by less-than-legal methods, and with a sample of pus from an excised bubo, was almost immediately able to isolate a bacillus that seemed like the causal agent. Yersin's conclusive reports came almost concurrently with Kitasato's, but many believe that what Kitasato had isolated was in fact a pneumococcus, not the plague bacillus. The bacillus is now called *Yersinia pestis*. In true pasteurian fashion, Yersin set out to attenuate the bacillus and develop an anti-plague serum, successfully treating his first plague patient, a Chinese seminary student, in 1896. See also **Kitasato, Shibasaburo (1852–1931)**.

Yersin began building laboratory facilities in Nha Trang, Indochina, in 1895. In 1905 these facilities officially became l'Institut Pasteur de Nha Trang. Nha Trang would be Yersin's home until his death in 1943. Though much evidence of the French colonial era has been removed from the face of contemporary Vietnam, Yersin's tomb is maintained as a shrine and streets and buildings still bear his name.

Details of Yersin's experiences, from his medical schooling, his work in Paris, to his explorations in Indochina and his research there, are known to us thanks to a collection of nearly 1000 letters he wrote faithfully to his mother and sister until 1932.

SUZANNE BOARD, Toronto, Ontario, Canada

YERSINIOSIS. See **Foodborne Diseases**.

YEW TREES. Members of the family *Taxaceae* (yew family), these evergreen trees and shrubs have needlelike leaves, are very hardy and do well in most soils. Among conifers, the yews are distinctive in that a given tree is either male or female. Yews are considered among the best plants for hedges, having a very dense and evenly-distributed foliage. One disadvantage is that the yew grows more slowly than other plants suitable for hedges, such as the thujas or Lawson cypress. Hedges should not be overemphasized, however, because yews grow into medium-size trees as indicated by the accompanying table. Yews fall into four genera as indicated by the following list of principal species:

Chinese plum yew	*Cepholotaxus fortunei*
European or common yew	*Taxus baccata*
Japanese yew	*Taxus cuspidata*
Plum-fruited yew	*Podocarpus anidinus* (See entry on **Podocarps**.)
Prince Albert's yew	*Saxegothaea conspicua*

The yews grow abundantly in the British Isles, Europe, and parts of North America. The tree has been a favorite for hedges and gardens for many years, particularly in Britain and Europe. Possibly the oldest living tree in Europe is a yew at Fortingall in the Scottish Highlands. It is estimated to be about 1,500 years old. The common yew is found in the United States and Canada along the Pacific coast, southeastern Alaska, in the Sierra Nevada Mountains, through the northern states and in the Rocky Mountains. Often, the yew is found as a small tree or shrub. The Pacific yew or Oregon yew (*Taxus brevifolia*) can be considered a small forest tree, occurring on the Pacific slopes. It usually ranges in height from 20 to 40 feet (6 to 12 meters), but in some cases may reach as high as 70 feet

Fig. 1. Florida torreya (*Torreya taxifolia*) located in North Carolina. (*North Carolina Department of Natural and Economic Resources*.)

(21 meters). The Savin or Florida yew (*Taxus foridana*) is a species local to western Florida. See Fig. 1.

The outer bark of most yews is thin with many breaks. It peels away easily. The fruit is pulplike, bright red, showy, and full of seeds. The leaves are olive green, pointed, and leather-like to the touch. The wood is hard and durable, with a red coloration. In the past, it has found limited use for archer bows, canoe paddles, and some forms of cabinet work, when available.

The plum yews are set apart from the other yews in that the fruit is a nut, which is enclosed in a fleshy container that looks something like a plum — hence the name. Their leaves are also much longer, more widely spaced and of a lighter-green color. The plum yews are relatively small, open, and irregularly shaped trees. The Chinese plum yew is used extensively in gardens and landscaping, particularly in Europe. The smaller Japanese plum yew is also a favorite of some gardeners. As one authority points out, it is difficult to visualize the fruits of these yews as "cones."

Torreya california, the California nutmeg tree, is also a plum yew. It was named after the botanist whose name is also associated with the Torrey pine. The tree is much sharper in texture than the Chinese plum yew, but the fruit is similar. The tree is a native of California woodlands.

A record specimen of the *Torreya taxifolia* (Florida torreya) is shown in the accompanying figure.

Record yews growing in the United States are shown in Table 1.

YIELD POINT. The minimum unit stress at which a structural material will deform without a significant increase in the load is called the yield point. Some materials do not have a yield point and in others it is not a well-defined value. Consequently, in these cases it has become common practice to use a quantity called the yield strength. The yield strength is the unit stress corresponding to a specific amount of permanent unit deformation.

YOHKOH SOLAR OBSERVATORY. See **Space Science Missions: Sun**.

YOKE. 1. The yoke of a motor or generator is the supporting and magnetic structure back of the poles, i.e., it is the part of the machine through which the flux passes in going between poles at the ends away from the armature. 2. The yoke of a magnetic-deflection cathode ray tube is the frame upon which is wound the horizontal and vertical deflecting coils.

YOLK GLAND. A portion of the reproductive system of the female by which yolk is secreted. In some animals called the vitellarium.

YOLK SAC. An accessory embryonic membrane formed in the vertebrates as an enveloping structure around the yolk of the egg. It is connected with the mid gut of the embryo and serves for the absorption of nourishment during embryonic life, and in some species, notably the fishes, after the individual has become active. The wall of the structure is composed of the same germ layers that form the gut, a lining endoderm, and a covering

TABLE 1. RECORD YEW TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Florida yew (1986) (*Taxus floridana*)	25	64	20	6.1	26	7.9	Florida
Pacific yew (1989) (*Taxus brevifolia*)	180	457	54	16.5	30	9.1	Washington

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

of splanchnic mesoderm. In the latter blood and blood spaces develop at an early period, later forming a network of vitelline vessels from which blood flows into the body of the embryo by way of a pair of large omphalomesenteric veins. Branches of the arterial system of the body extend into this plexus, completing a cycle for the transportation of the absorbed food to the developing body.

The yolk sac persists even in the mammals, where yolk is usually not present. In these forms it serves for the absorption of materials from the surrounding uterus during early development and is involved in the development of the circulatory system. It soon becomes a vestige, however, as its functions are taken over by other membranes.

YOSEMITE. A deeply U-shaped portion of a glacial valley, with sheer walls, hanging troughs, and a wide almost level floor, encountered in the Sierra Nevada Mountains of California. These formations resemble the Yosemite Valley, California.

YOUDEN SQUARE. If in a balanced incomplete block design the number of blocks is equal to the number of treatments, it is possible to arrange the blocks as columns of a rectangular array in such a way that each treatment occurs just once in every row. The corresponding experimental design is known as a Youden square (cf. **Latin Square**) and differences between rows as well as differences between columns can be eliminated from the estimate of error.

YOUNGER DRYAS. The period from approximately 10 800 to 9600 BC when climate in the region around Greenland cooled by 5°–7 °C (41°–45 °F) within a few decades and recovered with similar rapidity at the end of the period; named for the expansion of the geographic range of the arctic herb *Dryas octopetala*. Evidence is accumulating for a wider, perhaps global, extent, but the Younger Dryas was most strongly felt around the North Atlantic Ocean. Changes in the thermohaline circulation of the oceans are widely believed to be implicated in the onset and ending of the Younger Dryas cooling. These were in turn associated with a switch to the St. Lawrence River as the major route for meltwater reaching the North Atlantic from the retreating continental ice cap. Other similarly rapid oscillations in climate are recorded through much of the last glacial in ice cores from Greenland and in marine sediment cores from the North Atlantic (Dansgaard–Oeschger events). The period since the Younger Dryas (the Holocene) lacks such extreme excursions.

YOUNG-HELMHOLTZ THEORY. The original theory of color vision. It assumes the existence in the eye of three mechanisms each sensitive to one of the three primary colors, red, green and blue. It accounts for some of the observed phenomena of color vision, but not for others. The theory is convenient for many purposes but has been modified by later students.

YOUNG INTERFERENCE EXPERIMENT. In 1801 Thomas Young made the epochal discovery of the interference of light waves, by means of an experiment which has become classic. Light from a narrow slit L falls on a plate in which are two parallel slits, A, B, very close together, so that from the further side of the latter there emerge two exactly similar wave trains. See Fig. 1. These overlap in the region beyond AB and produce interference. If a screen F is placed at some distance from AB, alternate bright and dark bands or fringes appear on it, parallel to the two slits. If a translucent screen is used (or in the case of white light, a plate of colored glass acting as a light filter), these bands may be viewed by means of a magnifier beyond it at E, or better, a low-power micrometer eyepiece, with which the width of the band-interval can be measured.

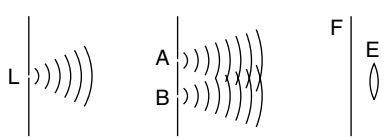

Fig. 1. Light from single source L gives rise to two wave trains at A and B, which produce interference fringes on screen F.

It is easy to show from the elementary theory of interference that if $AB = s$, if the distance from AB to F is x, and if the wavelength of the light is λ, the distance on the screen between any two consecutive dark bands or any two consecutive bright bands is $b = x\lambda/s$. Therefore if b, s, and x are measured, we have at once a means of determining the wavelength: $l = bs/x$.

Other devices have proved more satisfactory than the pair of slits, such as the biprism, Fresnel's mirrors, or Lloyd's mirror; each of which produces a double virtual image of the slit L to serve as the two wave-train sources A and B.

YOUNG'S MODULUS. A modulus of elasticity in tension or compression, involving a change of length. See also **Elasticity**.

YOUNG, THOMAS (1773–1829). Young was an English inventor and scientist. He earned his medical degree in 1800 and began practicing medicine. In 1801, however, he became a professor of natural philosophy at the Royal Institution and became recognized for his published lectures.

Young began researching doing experiments with light and his work supported the wave theory by his introduction of the principle of interference, which explained the bright and dark bands seen when light passes through two narrow slits. Young is also recognized for his later work in which he worked with Egyptian Hieroglyphics and showed that the markings were not just pictorial but phonetic sounds.

See also **Young-Helmholtz Theory**; **Young Interference Experiment**; and **Young's Modulus**.

J. M. I.

YOUTH (Geological). From a topographical standpoint, the youth stage is the first stage of the cycle of erosion in the topographic development of a landscape or region, during which stage the original surface or structure remains the dominant feature of the relief. The stage is typified by a few, small and widely spaced young streams; by broad, flat-top interstream divides and upland surfaces, only modified in a minor way by erosion; by partially developed or poorly integrated drainage systems, the latter having numerous swamps and shallow lakes; and by rapid and progressive increase of local relief, with sharp landforms, steep and irregular slopes, and a surface considerably above sea level.

From a coastal standpoint, the youth stage is that phase of development of a shore, shoreline, or coast that is typified by an ungraded profile of equilibrium. In the case of a shoreline of submergence, an irregular or crenulate outline, vigorous wave action, formation of sea cliffs, and associated erosional forms will be present, as well as a steep offshore profile, and the presence of bays, promontories, offshore islands, spits, bars, and other fairly minor irregularities. In the case of a shoreline of emergence, there usually will be a straight and simple outline, larger waves breaking well offshore, small waves coming to land to produce a nip or low cliff, and the formation of barrier beaches, lagoons, and marshes.

From the standpoint of a stream, the youth stage is the first stage in the development of a stream, a stream that has just commenced its work of erosion and is increasing steadily both in vigor and efficiency, enabled to erode its channel and not yet having reached a graded condition. The stream in this stage is typified by an ability to carry a load greater than what it is carrying; by forming a deep, narrow, steep-walled, V-shaped valley, gorge, or canyon with a steep and irregular gradient and rocky outcrops; by numerous waterfalls, rapids, and lakes; by a swift current and clear water; by a few, short, straight tributaries; by an ungraded bed; and by the absence of flood plains.

YTTERBIUM. [CAS: 10361-91-8] Chemical element symbol Yb, at. no. 70, at. wt. 173.04, thirteenth in the Lanthanide Series in the periodic table, mp 819 °C, bp 1196 °C, density 6.966 g/cm^3 (20 °C). Elemental ytterbium has a face-centered cubic crystal structure at 25 °C. The pure metallic ytterbium is silver-gray in color and is stable in moist or dry air up to 200 °C, after which oxidation occurs. The metal is readily dissolved by dilute and concentrated mineral acids. The metal dissolves in liquid NH_3 to yield a dark-blue color. There are seven natural isotopes ^{168}Yb, ^{170}Yb through ^{174}Yb, and ^{176}Yb. Ten artificially-produced isotopes have been identified. Ytterbium is one of the least abundant elements of the rare-earth group

and 53rd among all elements occurring in the earth's crust. The element was first identified by J.D.G. Marignac in 1878. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{13} 5s^2 5p^6 5d^1 6s^2.$$

Ionic radius Yb^{2+} 1.00 Å; Yb^{+3} 0.88 Å. Metallic radius 1.940 Å. First ionization potential 6.25 eV; second 12.18 eV. Other important physical properties of ytterbium are given under **Rare-Earth Elements and Metals**.

The principal sources of ytterbium are euxenite, gadolinite, monazite, and xenotime, the latter being the most important. Ytterbium is separated from a mixture of yttrium and the heavy Lanthanides by using the sodium amalgam reduction technique. Ytterbium metal is obtained by heating a mixture of lanthanum metal and ytterbium oxide under high vacuum. The ytterbium sublimes and is collected on condenser plates whereas the lanthanum is oxidized to the sesquioxide.

To date, the major uses of ytterbium have been in applied and fundamental research. The element and its compounds have been used in magnetic "bubble" domain devices (ytterbium orthoferrite), in phosphors to convert infrared to visible light, in lasers, and radioisotope ^{169}Yb has found application in portable industrial and medical radiographic units.

YTTRIUM. [CAS: 7440-65-5]. Yttrium is pronounced as IT-re-em. Chemical element symbol Y, at. no. 39, at. wt. 88.905, periodic table group 3, mp 1522 °C (2772 °F), bp 3,338 °C (6040 °F), density 4.469 g/cm^3 (20 °C). Most of the properties of yttrium are similar to those of the heavy rare-earth elements, falling between gadolinium [CAS: 7440-54-2] and erbium [CAS: 7440-52-0]. Elemental yttrium has a close-packed hexagonal crystal structure at 25 °C. The pure metallic yttrium is silver-gray in color, retaining a luster in air up to about 400 °C, above which it oxidizes to Y_2O_3. The metal is dissolved by most mineral acids, but is relatively inert in a 1:1 mixture of concentrated HNO_3 and 48% hydrofluoric acid. Yttrium is capable of working common metallurgical fabrication procedures. The metal is immiscible with liquid or solid uranium metal. It has a low thermal-neutron-absorption cross section and a low acute-toxicity rating. Natural yttrium is composed of only one isotope ^{89}Y. The most stable radioisotopes are ^{88}Y which has a half life of 106.65 days and ^{91}Y with a half life of 58.51 days. All the other isotopes have half lifes of less than a day except ^{87}Y which has a half life of 79.8 hours. The dominant decay mode below the stable ^{89}Y is electron capture and the dominant mode after it is beta emission. Fourteen artificial isotopes have been identified. See also **Radioactivity**. In terms of abundance, yttrium is present on the average of 33 ppm in the earth's crust and potentially is as plentiful as cobalt.

Yttrium (named for *Ytterby*, a Swedish village near Vaxholm) was discovered by Johan Gadolin in 1794 and isolated by Friedrich Wohler in 1828 as an impure extract of yttria through the reduction of yttrium anhydrous chloride (YCl_3) with potassium. Yttria (Y_2O_3) is the oxide of yttrium and was discovered by Johan Gadolin in 1794 in a gadolinite mineral from Ytterby.

In 1843 Carl Mosander was able to show that yttria could be divided into the oxides (or earths) of three different elements. "Yttria" was the name used for the most basic one and the others were named erbia and terbia.

A quarry is located near the village of Ytterby (a village in Sweden near Vaxholm) that yielded many unusual minerals that contained rare earths and other elements. The elements erbium, terbium, and ytterbium, and yttrium have all been named after this same town.

Electronic configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^1 5s^2$. Ionic radius $Y^3 + 0.900$Å. Metallic radius 1.801Å. First ionization potential 6.38 eV; second 12.24 eV. Other important physical properties of yttrium are given under **Chemical Elements**; and **Rare-Earth Elements and Metals**.

Residues from uranium mining operations in Canada have been a major source of yttrium. Xenotime (YPO_4) found in Malaysia is another source, as well as the ion-adsorption clay minerals in China. Some apatite deposits are unusually rich in yttrium and it also is found in gadolinite, euxenite, and samarskite.

In recovering yttrium, mixed rare-earth minerals or wastes are dissolved in HNO_3 or H_2SO_4. Liquid-liquid organic ion-exchange solvent extraction cells then separate a pure yttrium fraction, usually precipitated as an oxalate and then calcined to the oxide. The metal is obtained by metallothermic reduction, using calcium mixed with YCl_3 or YF_3 in a sealed retort at a temperature in excess of 1,550 °C. Alloys of yttrium and cobalt, or yttrium and magnesium have been deposited out of a molten electrolyte BaF_2-LiF-YF_3.

Lunar rock samples from the Apollo program have a relatively high yttrium content.

The major uses of yttrium are as phosphors in color television, computer monitors, trichromatic fluorescent lights, x-ray intensifying screens and temperature sensors. Yttrium oxide stabilized zirconium oxide is used as oxygen sensors for automobile engines and in iron making, wear-resistant and corrosion-resistant cutting tools, abrasives, high temperature refractories for continuous casing nozzles, jet engine coatings, simulated diamond gemstones (i.e. cubic zirconia), and as a solid electrolyte in solid oxide fuel cells (SOFC). Yttrium aluminum garnets are used as laser crystals for industrial cutting and welding, medical and dental surgery, temperature and distance sensing, photochemistry, photoluminescence, digital communication and non-linear optics.$YBa_2Cu_3O_7 - x$ is an important high temperature ceramic superconductor with a 90 K superconducting transition temperature. It is primarily used in the form of thin films for superconducting electronics (such as SQUIDS, MRI and NMR coils, wireless communication subsystems and digital instruments) and as superconducting wires and tapes for power transmission lines, motors and generators, transformers, current limiters, magnetic separation, research magnet systems and current leads. Yttrium-iron garnets find use as microwave bandpass filters, circulators, and isolators in electronic and communications circuitry. Y_2O_3 is used as a metallurgical dispersion hardening agent in nickel-based superalloys made by powder metallurgy techniques. Yttrium metal also is specified in several cobalt-base superalloys in which it improves hot corrosion (sulfidation) resistance at high temperatures. When used in iron-chromium-aluminum alloys, yttrium improves workability and adds resistance to sag when the alloys are used as electrical-heating elements. The metal also is applied as cladding to rotating turbine engine parts to obtain superior oxidation resistance. Yttrium also has been used in permanent magnets, YCo_5, and shows great promise. These magnets are second only to $PrCo_5$ as the most powerful permanent magnet materials developed to date, far exceeding alnico and other more conventional materials.

Chemistry and Compounds. Yttrium hydroxide, $Y(OH)_3$ is precipitated by NH_4OH from solutions of yttrium salts. It differs in properties from the lanthanide hydroxides, both structurally and chemically, in its ability to absorb atmospheric CO_2. Yttrium oxide, Y_2O_3, is obtained by heating the hydroxide or oxy-acid salts; it forms mixed oxides when heated with other oxides, such as Fe_2O_3 and TiO_2. Yttrium also forms a peroxide, Y_4O_9, obtained in hydrated form by treatment of yttrium solutions with hydrogen peroxide.

All four halides are known. The fluoride, YF_3, is readily formed by action of a fluoride on an yttrium nitrate solution. There is an oxyfluoride, YOF, formed by high-temperature, low-pressure heating of the mixed oxide and fluoride. Complex fluorides, containing $[YF_6]^{3-}$ exist; the cryolite minerals are of this composition. The group, $-YF_4$ is found in double salts formed by YF_3 and the alkali fluorides. The chloride, YCl_3, is formed as a hydrate by action of HCl solution upon the hydroxide. It may be dehydrated by slow heating; rapid heating gives the oxychloride, YOCl. The bromide, YBr_3, is formed as a hydrate by action of HBr upon the hydroxide. Its dehydration requires heating under vacuum. The iodide, YI_3 is best prepared from the anhydrous chloride, by reacting with Hl and I_2.

Both normal and mixed carbonates are known. The former is precipitated, as $Y_2(CO_3)_3 \cdot 3H_2O$ from Y^{3+} solutions by alkali metal carbonates, which in excess dissolve the precipitate to form a soluble hydrated double carbonate. The oxycarbonate is also a double molecule, $3Y_2(CO_3)_3 \cdot 2Y(OH)_3$, formed by action of CO_2, upon the hydroxide.

The nitrate, $Y(NO)_3$ exists as a number of hydrates. The hexahydrate formed by action of HNO_3 upon the hydroxide, is dehydrated at 100 °C to give the trihydrate and the anhydrous salt. However, other hydrates are known, as well as double nitrates (especially with the lanthanide elements) and oxynitrates, of the general formula, $xY_2O_3 \cdot yN_2O_5 \cdot zH_2O$.

Yttrium hydroxide forms a hydrated sulfate with H_2SO_4, which is dehydrated on heating. It forms double sulfates with alkali and ammonium sulfates.

The carbide, formed from the oxide and carbon in the electric furnace, appears to have the composition, YC_2. It yields acetylene and other hydrocarbons upon hydrolysis.

Health and Safety

Compounds that contain this element are rarely encountered by most people but should be considered to be highly toxic even though many compounds pose little risk. Yttrium salts may be carcinogenic. This element is not normally found in human tissue and plays no known biological role.

See references listed at ends of entries on **Chemical Elements**; and **Rare-Earth Elements and Metals**.

YUCCA. See **Palm Trees**.

YUCCA BORER *(Insecta, Lepidoptera)*. A giant skipper, *Megathymus yuccae*, whose larva bores in the stem and root of yucca plants. Several species of these insects are known, expanding from $2–3\frac{1}{2}$ inches (5 to 9 centimeters) in the adult stage. While yucca seems to be the prevailing food plant, some species are known to attack agave. They are limited in distribution to the southern states and south into Central America with the exception of one that has been taken in central Colorado and western Nebraska.

YUCCA MOTH *(Insecta, Lepidoptera)*. A small moth, also commonly called the pronuba moth from the name of its genus. It lives in the flowers of yucca,depositing its eggs in the ovary of the plant and then pollinating the flower. The developing larva eats the seeds, but since many more are formed than it is capable of consuming, the exchange is beneficial to the plant. Several species of these moths are known. All belong to the same genus, whose early name, *Pronuba*, has been supplanted by another, *Tegeticula*. Yuccas are also frequented by moths of the genus *Prodoxus*, which are of no service in pollinating the flowers. They are called false yucca moths.

YUKAWA, HIDEKI (1907–1981). Yukawa was a Japanese physicist who did research in the field of quantum physics. He graduated from Kyoto University. He is best known for predicting "heavy quantum" for a particle heavier than an electron. He is best known for his insight into mesons providing an explanation of the force responsible for binding together the atomic nucleus. For this insight and his research work, Yukawa won the Nobel Prize in Physics in 1949.

Yukawa's other awards include the Imperial Prize of the Japan Academy in 1940 and the Lomonosov Gold Medal of the USSR Presidium of the Academy of Sciences in 1964.

See also **Yukawa Potential**.

J. M. I.

YUKAWA POTENTIAL. A potential function of the form $V = (V_0/r)(e^{-r/b})$. It is used to describe the meson field about a nucleon. The Yukawa potential is employed rather frequently as one shape of nuclear potential well that can be used in attempts to fit theory with experimental results, for example, in high-energy scattering. It is characterized by (1) infinite strength at $r = 0$, (2) an exponential tail extending with appreciable strength to larger r rather than a Coulomb potential. See also **Nuclear Forces**; and **Particles (Subatomic)**.

Z

ZADOKS SCALE. See **Scale**.

ZANZIBAR CURRENT. See **Ocean Currents**.

ZEBRA. See **Horses, Asses, and Zebras**.

ZEBRA FISH *(Brachydanio rerio)*. A popular, easy-to-breed aquarium fish highlighted by its four blue longitudinal stripes. The species reaches a length of 4.5 cm and is distributed in central India. The zebra fish, as of late 1990, was under consideration by molecular biologists as an organism that may one day be the vertebrate *Drosophila* as a model for studies of embryology and developmental biology.

ZEBRA TIME. The same as mean time at the Greenwich meridian. The system is used in communication and for synchronized reckonings. Sometimes called Z time. The hour 2400 Zebra time is equivalent to 0300 (Moscow standard time); 0800 (Manila standard time); 0900 (Tokyo standard time); 1000 (Sydney standard time); 1400 (Hawaiian standard time); 1600 (Pacific standard time); 1700 (Mountain standard time); 1800 (Central standard time); 1900 (Eastern standard time).

ZEDOARY. A perennial herb (*Curcuma zedoaria* Rosc.) of the family *Zingiberaceae*. The dried product prepared from the rhizomes is used as a spice and in the formulation of liqueurs. The bark extract has been used in the manufacture of bitters. There is no extensive use for the essential oil, which is obtained by steam distillation of the rhizomes.

The plant, native to India, is cultivated for edible purposes. The rhizomes are thick and tuberlike and are edible, as are the very large leaves. Flavoring products prepared from zedoary are described as having a warm and camphoraceous odor and a warm, spicy, and slightly bitter taste.

ZEEMAN EFFECT. An effect of a moderately intense magnetic field upon the structure of the spectrum lines of a gas when subjected to its influence. The phenomenon, sought unsuccessfully by Faraday and finally observed by Zeeman in 1896, consists in the splitting up of each line into two or more components. In the simpler cases, when the source is viewed at right angles to the field, there are three components, of which the middle one has the same frequency as the unmodified line. This component is plane-polarized to vibrate parallel with the field, while the two side components vibrate at right angles to the field. When the source is viewed in the direction of the field, there are only two components, displaced in opposite directions, and circularly polarized in opposite senses. (See also **Polarized Light**.) These phenomena constitute the so-called "normal" Zeeman effect.

With most lines, however, an anomalous Zeeman effect is observed and the number of components is greater, in some cases reaching twelve or fifteen. They are symmetrically arranged and symmetrically polarized. The displacements, as in the simpler case, are proportional to the magnetic field intensity H, and are always expressible, in wave numbers, as rational multiples of the displacement in the normal effect, which is $4.67 \times 10^{-5} H$ (reciprocal centimeter), a quantity known as the "Lorentz unit." The Zeeman effects observed in sun spots give valuable information as to the magnetic conditions in those areas.

Closely related to the Zeeman effect are two others, the Paschen-Back effect, produced by very strong magnetic fields, and the Back-Goudsmit effect, observed with the spectra of elements having a nuclear magnetic moment, such as bismuth. See also **Electron Theory**; **Paschen-Back Effect**; and **Stark Effect**.

ZEEMAN, ERIK CHRISTOPHER (1925–). Sir Erik Christopher Zeeman is a Japanese-born British mathematician known for work in geometric topology and singularity theory.

Zeeman was born in Japan to a Danish father and a British mother. He and his parents moved to England one year after his birth. After being educated at *Christ's Hospital School* in Horsham, West Sussex, he served as a Flying Officer with the Royal Air Force from 1943 to 1947. He studied mathematics at Christ's College, Cambridge, but had forgotten much of his high-school mathematics while serving for the air force. He received a B.A. and Ph. D. from the University of Cambridge. After working at Cambridge (during which he spent a year abroad at University of Chicago and Princeton as a Harkness Fellow) and the Institut des Hautes Etudes Scientifiques, he founded the Mathematics Department and Mathematics Research Centre at the new University of Warwick in 1964, www.maths.warwick.ac.uk/.

Zeeman is not only known for this mathematical contribution but also for being an excellent educator. He remained a Professor at Warwick until 1988, when he became Principal of Hertford College, Oxford. Zeeman was elected as a Fellow of the Royal Society in 1975. He gave many mathematical talks on radio and television to reach a broader audience feeling that many gifted were amongst the educationally deprived population. He was honored by Queen Elizabeth II knighting him in 1991 for his role in advancing mathematics education. On Friday 6 May 2005, the University of Warwick's Mathematics and Statistics building was renamed the Zeeman building in his honour.

Zeeman's main contribution to mathematics was in topology, particularly in the piecewise linear category, and dynamical systems. However, he is better known to the general public for his contribution to, and spreading awareness of catastrophe theory, which was due initially to another topologist René Thom. He was especially active encouraging the application of mathematics, and catastrophe theory in particular, to biology and behavioural sciences. See also **Chemical Elements**; **Electron Theory**; and **Zeeman Effect**.

J. M. I.

ZEIN. Prolamine protein in maize (homologous to gliadin in wheat) may make up to 50% of the grain proteins. It is a protein of low nutritional value (and thus undesirable) because of the low lysine and tryptophan content. It is deposited in zein bodies at the place of synthesis. In the high-lysine maize varieties (*opaque, floury*), prolamines are very low and nonprolamine proteins increase. See also **Starch**.

ZEISBERG CONCENTRATOR. A nitric acid concentrator, consisting of a packed tower, into which weak nitric acid vapors are introduced. Some steam is admitted into the bottom, and strong nitric acid vapors are discharged from the top to a condenser.

ZEISEL DETERMINATION. Cleavage of methoxy and ethoxy groups with boiling hydriodic acid [CAS: 10034-85-2], distillation of the alkyl iodide into alcoholic silver nitrate, and gravimetric determination as silver iodide [CAS: 7783-96-2]. Alternatively, the alkyl iodide is oxidized to form iodate, and the iodine [CAS: 7553-56-2] liberated by addition of potassium iodide [CAS: 7681-11-0] is titrated.

ZEISEL REACTION. The demethylation of an organic compound by treatment with hydriodic acid [CAS: 10034-85-2], which leaves a hydroxy group in place of the methoxy group, and forms methyl iodide [CAS: 74-88-4], which may readily be determined quantitatively, as in the study of the amount of methoxy groups present.

ZEITGEBER. The rhythmic external signal for circadian change. See also **Circadian Clock**.

ZELLWEGER'S SYNDROME. A rare familial condition in which are found severe hypotonia, abnormalities of the central nervous system, hepatic (liver) cirrhosis, and malformation of the skeleton. Persons with this malady seldom live beyond age 6 months. For persons who survive to an older age, there is frequently mental retardation and display of severe mitochondrial abnormalities. Hanson et al. (1980) have described the syndrome as a unique "experiment of nature" in which the role of the mitochondria in bile acid synthesis could be assessed in vivo.

ZENER CURRENT. The current through an insulator in a very intense electric field, sufficient to excite an electron directly from the valence band to the conduction band.

ZENER DIODE. A type of silicon diode that acts like a rectifier until the applied voltage reaches the avalanche breakdown voltage (zener voltage). At this point, the diode becomes conducting. The voltage drop across the diode remains essentially constant and independent of current. The diode is used in voltage-limiting circuits and power supplies. Zener diodes are now used in precise reference signals. A potentiometric instrument can be no more accurate than the calibrated (standard) source of emf against which the unknown potential is compared. Standard cells and a variety of batteries calibrated against standard cells have been of prime use, but in recent years, batteries such as the mercury cell are used directly as a standard when accuracy requirements permit. Since the 1960s, the zener diode used in an appropriate circuit has become most useful by offering low cost, very long life, small size, and accuracies equivalent or better than standard cells, particularly over long period. A typical circuit using zener diodes is shown in Fig. 1. The resistors R_1, R_2, R_3 and the dynamic resistance of *CR1* constitute a balanced Wheatstone bridge which tends to eliminate variations in V_{supply} from the nodes A and B. *CR1* and *CR2* are in a conventional cascade configuration because R_2 is inherently large compared to R_1 and R_3. *CR2* is also a temperature-compensated zener diode, and the resulting standard emf can be held to within 0.02% over a normal working range of supply voltage and ambient temperature.

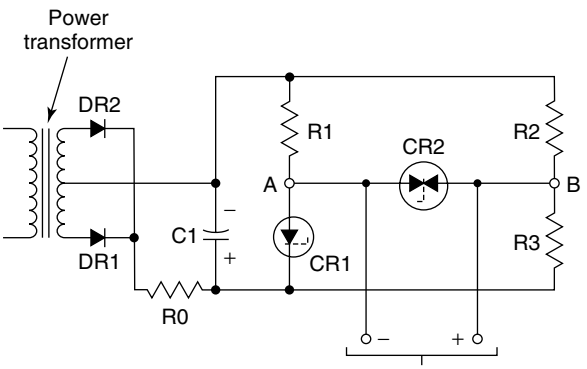

Fig. 1. Bridge-type circuit in which zener diode is used as constant-voltage source.

ZENER VOLTAGE. 1. The field required to excite the Zener current, of the order of 1 volt per unit cell, or 10^7 volts/centimeter. 2. The voltage associated with that portion of the reverse volt-ampere characteristic of a semiconductor, wherein the voltage remains substantially constant over an appreciable range of current values.

ZENITH. The point on the celestial sphere directly overhead is the *observer's zenith*. The *astronomical zenith* is defined as the point where the plumb line extended up from the surface of the Earth will intersect the celestial sphere. Owing to the fact that the plumb line may be affected by local gravitational effects, such as large mountains in the vicinity, the *geographical zenith* is the point where a line perpendicular to the surface of a smooth Earth would intersect the celestial sphere. The angular distance between the astronomical and geographical zenith is the station error of the point on the surface of the Earth. Because of the fact that the Earth is an oblate spheroid rather than a perfect sphere, neither the plumb line nor a perpendicular to the surface of the Earth will pass through the geometrical center of the Earth unless the observer is either at one of the poles or on the equator. The *geocentric zenith* is defined as the point where a line extended from the center of the Earth through the observer will intersect the celestial sphere. The angular distance between the astronomical and geocentric zenith is the reduction of latitude for the observer. See also **Celestial Sphere and Astronomical Triangle**.

ZENITH TELESCOPE. This instrument, as the name implies, is designed for use at or very close to the zenith. A telescope is mounted in the same manner as the meridian circle, i.e., in the altazimuth form, with the azimuth so fixed that the instrument is always in the plane of the meridian. In place of the accurate circles for measuring altitude that are to be found on the meridian circle, this instrument carries a very accurate level so adjusted that the bubble is in the center of the tube when the telescope is pointing at the zenith. The reticle of the instrument carries, in addition to the set of wires parallel to the meridian, as in the meridian circle, two wires parallel to the axis of rotation, i.e., perpendicular to the meridian. One of these wires is fixed, and when the instrument is in proper adjustment, with the level bubble in the center of the tube, the fixed wire is in the plane of the prime vertical, i.e., passes through the zenith. The other wire may be moved by means of a fine screw, which is parallel to the meridian. The head of this screw is accurately calibrated so that the distance of the movable wire from the zenith wire may be determined in seconds of arc.

The zenith telescope is used primarily for the accurate determination of terrestial latitude by what is commonly known as Talcott's method. In Fig. 1, we have a representation of the celestial sphere drawn in the plane of the observer's meridian $HPZQH'$. HOH' is the plane of the horizon, Z is the astronomical zenith, P is the pole of rotation, and Q is the direction of the equator. HP is the altitude of the pole, and hence, by definition, is the astronomic latitude of O. Inspection of the figure shows that QZ, the declination of the zenith, is also equal to ϕ.

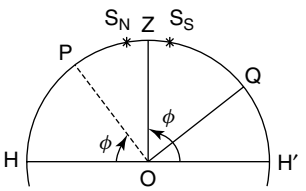

Fig. 1. Principal parameters of zenith telescope.

For the purpose of determining QZ, a pair of stars, S_s and S_n, are selected that have approximately the same right ascension and hence will cross the meridian within a short time of each other. The declinations of the stars are so selected that one will pass just south of the zenith and the other just north. Such pairs of stars, known as Talcott pairs, have been selected and their declinations accurately determined by various observatories. Of course, for the selection of the proper pairs to be used for a particular station, the latitude of that station must be approximately determined in advance by any of the methods discussed under latitude.

At the time that one of the stars is approaching the meridian, the observer watches in the eyepiece of the zenith telescope, and when the star appears, he sets the movable wire upon the star and keeps it there until the star has crossed the meridian. The reading of the screw gives the distance of the star north or south of the zenith, either S_nZ or S_sZ, depending upon which star is observed first. The second star is then observed and the other zenith distance determined in the same manner. From the value of the measured zenith distances and the declinations of the stars, the value of the declination of the zenith, and hence the latitude, can be accurately determined.

The great advantage of this method is that both stars are observed close to the zenith, so that the correction for astronomical refraction is very small in either case. Furthermore, since one star passes north and the other south of the zenith, the refraction corrections practically neutralize each other. The measurement of the zenith distance by means of the screw can be very

accurately made. The disadvantages of the method are that it requires the use of the accurately adjusted fixed instrument, and the declinations of the stars must be very accurately known.

Observations of this character are constantly being made at various stations all over the world for the purpose of determining the variation of latitude. See also **Celestial Sphere and Astronomical Triangle**; and **Telescope (Astronomical-Optical)**.

ZEOLITE GROUP. To the zeolite group of minerals belong a number of hydrous silicates of aluminum which also ordinarily contain sodium or calcium, but rarely they may carry barium, strontium, magnesium, and potassium. These minerals are not related crystal-lographically as they occur in the isometric, orthorhombic, hex-agonal, and monoclinic systems, but they are all characterized by the presence of water, up to 10 or 20%, which is easily released with the application of heat. They are all rather soft minerals, hardness, 3.5–5.5; of low specific gravity, 2.0–2.5, and they will decompose readily upon treatment with acid, most of them yielding a gelatinous mass.

The easy fusion, together with the rapid expulsion of water, is responsible for the name of this interesting group; it is derived from the Greek words to boil and a stone, hence zeolite, "a boiling stone." The zeolites are secondary minerals, usually found filling fissures and cavities in the more basic igneous rocks as basalt, and gabbro, but occasionally in the more acidic types as granite or in gneisses. The following members of the zeolite group are described under **Analcime**; **Chabazite**; **Harmotome**; **Heulandite**; **Natrolite**; **Phillipsite**; **Scolecite**; and **Stilbite**.

See also **Molecular Sieve**.

ZEOLITE SOFTENING. See **Feedwater (Boiler)**.

ZEOLYTIC CATALYST. See **Petroleum**.

ZEOMORPHS. See **John Dories**.

ZEPPELIN. See **Dirigibles and Airships**.

ZEREWITINOFF DETERMINATION. The Zerewitinoff determination or Zerevitinov determination is a quantitative chemical test for the determination of active hydrogens in a chemical substance. A sample is treated with methylmagnesium iodide [CAS: 917-64-6] which reacts with any acidic hydrogen atom to form methane [CAS: 74-82-8]. This gas can be determined quantitatively.

ZERO. A number symbolized by 0. If a is any other number, its properties are: $a \pm 0 = a$; $a \times 0 = 0$; $a^0 = 1$; $0/a = 0$, if $a \neq 0$. Division by zero is prohibited, for this operation is undefined. Certain other operations involving zero give ambiguous results known as indeterminate forms. They can be interpreted by the methods of differential calculus.

A zero matrix is usually called *null*. For the zero of a function, see also **Function**.

ZERO-BASED CONFORMITY. See **Conformity**.

ZERO-BASED LINEARITY. See **Linearity**.

ZERO-BEAT RECEPTION. See **Homodyne Reception**.

ZERO ERROR. The error of a device operating under the specified conditions of use when the input is at the lower range-value. The term *zero shift* is often used to represent a change or drift in zero error with time.

ZERO GRAVITY. The absence of gravitational effects — either as a result of nullifying gravitational attraction, or counterbalancing gravitational attraction with centrifugal force. A zero-gravity switch actuates when a condition of weightlessness occurs. See also **Weightlessness**.

ZERO-ORDER REACTION. A reaction that has a constant rate, as in the case of certain gases reacting on the surface of a solid when it is almost entirely covered. Under such conditions, the reaction rate may be independent of pressure, and thus, the process is kinetically of zero order.

ZERO POINT ENERGY. The kinetic energy remaining in a substance at the absolute zero point of temperature. According to quantum mechanics, a simple harmonic oscillator does not have a stationary state of zero kinetic energy. The ground state has still one half quantum, hv, of energy, and the motion corresponding thereto. This agrees with the uncertainty principle, which does not permit the oscillator particle to be absolutely at rest exactly at the origin. In solids the zero-point energy is distributed in the normal modes of lattice vibration, and may be an appreciable term in the binding energy of the crystal, especially in hydrogen, helium, rare gases, etc. The motion may be observed in x-ray diffraction, but does not contribute to electronic resistivity.

ZERO POINT ENTROPY. According to the third law of thermodynamics (see also **Thermodynamics**), the entropy of a system in equilibrium at the absolute zero must be zero. Such systems, as for instance a glass, which can have finite entropy at absolute zero are not in thermodynamic equilibrium.

ZEROTH LAW. See **Thermodynamics**.

ZERO TOLERANCE. (1) Limit for a pesticide residue in food that is assumed to be zero and therefore any detectable residue is deemed illegal. Zero tolerances are used by some regulatory systems, e.g., in the United States, where no maximum residue limits have been established for particular pesticide/crop combinations (IUPAC). (2) Term used to describe a non-discretionary rules enforcement policy. Under a system of zero tolerance, persons in positions of authority–who might otherwise exercise their discretion in making subjective judgments regarding the severity of a given offense–are instead compelled to impose a pre-determined punishment. Zero tolerance policies are common in schools in the United States in regard to students bringing weapons, drugs or other contraband items to school. Zero tolerance policies are also common in U.S. workplace environments, most often for sexual harassment or Internet misuse.

ZETA POTENTIAL. The potential across the interface of all solids and liquids. Specifically, the potential across the diffuse layer of ions surrounding a charged colloidal particle, which is largely responsible for colloidal stability. Discharge of the zeta potential, accompanied by precipitation of the colloid, occurs by addition of polyvalent ions of sign opposite to that of the colloidal particles. The zeta potential of a particle can be calculated from electrophoretic mobility of the sample is known by Henry's Equation:

$$U_e = \frac{2\varepsilon\zeta f(ka)}{3\eta}$$

Where U_e is the electrophoretic mobility, ε is the dielectric constant of the sample, ζ is the zeta potential, $f(ka)$ is Henry's Function (most often used are the Huckel and Smoluchowski approximations of 1 and 1.5, respectively), and η is the viscosity of the solvent.

The zeta potential of a sample of colloidal particles is easily quantified using an LDV, or Laser Doppler Velocimeter. The LDV applies an electrical field of known strength across the sample, through which a laser is then passed. The electrophoretic mobility of the colloid will dictate the velocity with which the charged particles move, which will then induce a frequency shift in the incident laser beam. Using either the Huckel or Smoluchowski approximation for Henry's Function, the dielectric constant of the sample, the viscosity of the solvent, and finally the measured electrophoretic mobility, the zeta potential of the particles within the colloid can be calculated.

The primary relevance of the zeta potential of a colloid is as a relative measure of the stability of that system. The DLVO theory (named after Derjaguin, Landau, Verwey and Overbeek) for colloidal interactions dictates that a colloidal system will remain stable if and only if the Coloumbic repulsion arising from the net charge on the surface of the particles in a colloid is greater than the Van der Waals force between those same particles. See also **Van Der Waals Forces**. When the reverse is true, the colloidal particles will cluster together and from flocculates and aggregates (depending on the strength of the Van der Waals attraction and the presence/absence of Steric effects). See also **Steric Effects**. Since the higher the absolute zeta potential, the higher stronger the Coloumbic repulsion between the particles within a colloid, and therefore the lesser

the impact of the Van der Waals force on the colloid. See also **Colloid Chemistry**; and **Colloid Systems**.

ZIEGLER, KARL WALDEMAR (1898–1973). A German chemist who won the Nobel Prize for chemistry in 1963 with Giulio Natta for their discoveries in the field of the chemistry and technology of high polymers. A great deal of his work was concerned with the chemistry of carbon compounds and development of plastics. A recipient of the Swinburne medal from the Plastics Institute of London in 1964. After studying at Marburg he was a professor at Heidelberg.

ZIEGLER METHOD. Cyclization of dinitriles at high dilution in dialkyl ether in the presence of ether-soluble metal alkylanilide and hydrolysis of the resultant imino-nitril with formation of macrocyclic ketones in good yields.

ZIEGLER-NATTA CATALYSTS. The origin of the Ziegler-Natta catalysis dates back to 1953 when Ziegler discovered, at Muelheim, that some transition-metal compounds, eg, $TiCl_4$, used in combination with aluminium alkyls, could polymerize ethylene into linear polyethylene under mild conditions of pressure and temperature. In 1954, Ziegler's concept was applied by Natta, at the Polytechnic of Milan, to the regio- and stereoselective polymerization of propylene into a partially crystalline and stereoregular, previously unknown and unexpected polymer: isotactic polypropylene. These scientific breakthroughs, which allowed Ziegler and Natta to share the Nobel Prize in 1963, were quickly translated into industrial realities by Hoechst in 1955 and Montecatini in 1957, with the manufacture and commercialization of high-density polyethylene and isotactic polypropylene, respectively. See also **Polyethylene**; and **Polypropylene**. Since then, the development of catalysts related polymerization technologies and products has been relentless and is still in progress today. Over the years, the property envelope of polyolefins has been largely expanded by the generation of improved–innovative products that clearly outperform the previously available materials. For example, polypropylene modification with ethylene–propylene copolymers via sequential copolymerization of propylene and ethylene–propylene mixtures (*in situ* alloys) has led to the synthesis of multiphase copolymers offering an unprecedented balance between fluidity, rigidity, impact strength, transparency, etc. Starting from the initial few thousand tons, the production of polyolefins via Ziegler-Natta polymerization has grown exponentially in time, and today is approaching a global volume of 65 million tons. This is due not only to the intrinsic properties and performances of these materials but especially to the availability of ever more efficient, sophisticated and versatile catalyst systems, and resulting manufacturing processes. Following the initial (mid-1950s) studies on titanocenes, a family of homogeneous, single-site catalyst systems has more recently been developed, which are based on metallocenes or late transition-metal complexes that, in principle, offer a number of advantages over conventional Ziegler-Natta systems. However, despite this, heterogeneous Ziegler-Natta catalysts are still at the forefront of the scientific and, especially industrial, world since they still account for the majority of the global polyolefin market share.

In contrast to single-site catalysts, whose nature and structure, at least that of the precatalyst molecule, is well known and easily tunable, heterogeneous Z/N systems are rather complex, difficult to rationalize, and far from being completely understood. This peculiarity can be seen both as a drawback and a challenging stimulus and opportunity for both scientists and industrial researchers. The reason is that there is still a lot of room for the "classical" Ziegler-Natta systems to be further investigated and improved. For this reason, there is no doubt that these catalysts will remain a major area of research for the next years and will continue to have a bright commercial future.

Broadly speaking, a Ziegler-Natta catalyst system can be defined as a transition-metal compound bearing a metal–carbon bond able to promote a repeated insertion of olefin units and thus generate a macromolecular polyolefin chain. Usually, the catalyst system consists of the combination of two components: a transition-metal compound (most frequently a titanium halide) and a main group metal alkyl (generally an aluminium alkyl or alkyl halide), and can comprise additional components, eg, electron donors. The transition metal may be any of those in groups IV to VIII of the periodic table; the hydride or alkyl metals are those of groups I, II, and III.

Starting from the discoveries of Ziegler and Natta concerning the ability of the $TiCl_4/AlR_3$ mixture to promote the polymerization of ethylene and of propylene, continuous research in the field, mainly driven by industrial requirements, has led to the development of various families and generations of catalysts having a level of sophistication and performances one could only dream about at the time of their first discovery.

The polyolefin industry, aimed at both continuous simplification of polymerization technologies and product optimization–innovation, has fixed a number of ambitious objectives for the catalyst to target over the years, most of which have been achieved by the latest generations of catalyst systems:

- Very high mileage (chlorine content in the exreactor product less than ~50 ppm, preferably <10 ppm).
- Stereoregularity for polypropylene and the other 1-olefins (Isotactic Index, expressed as the polymer fraction insoluble in xylene at room temperature, higher than ~97%)
- Control of the most important polymer parameters like molecular mass (MW), molecular mass distribution (MWD), and comonomer incorporation, when required.
- Complete morphology control over both catalyst and polymer particles.

These spectacular achievements have been obtained thanks to the exploitation of several scientific and technological breakthroughs, and, especially:

- The active form of magnesium chloride.
- The stereoregulating effect of electron donors.
- The chemical route to the active form of magnesium chloride.
- The control of the morphology of the catalyst particle and the exploitation of the polymer–catalyst replication phenomenon.

Ziegler-Natta catalysts are robust, well-established versatile systems with which it is possible to synthesize a wide family of polyolefins, including both commodity and specialty products.

Among the positive attributes of Ziegler-Natta catalysts one can at least mention the following: low cost of both catalyst and cocatalyst; very high mileage; possibility to be used as drop-in components in all the existing polymerization technologies; possibility to control polymer MW and MWD in a broad range; tunable isospecificity, either very high or very low; complete control over morphology in terms of shape, size, surface area, and porosity of both catalyst and polymer particles.

ZIEGLER-NATTA POLYMERIZATION. Polymerization of vinyl monomers under mild conditions using aluminum alkyls and $TiCI_4$ (or other transition element halide) catalyst to give a stereoregulated, or tactic, polymer. These polymers, in which the stereochemistry of the chain is not random have very useful physical properties. See also **Ziegler-Natta Catalysts**.

ZIGZAG LIGHTNING. See **Lightning**.

ZIGZAG RIDGE. A continuous ridge that trends first in one direction, then in another, each alternating part being roughly parallel. Such a condition is formed by the converging of two ridges in one direction, each ridge converging with a different ridge in the opposite direction. Zigzag ridges are found in the Appalachian Mountains, where they resulted from truncation of plunging folds.

ZIMMERMANN REACTION. The reaction that occurs between methylene ketones and aromatic polynitro compounds in the presence of

alkali. When applied to 17-oxosteroids, the colored compounds formed can be used for the quantitative determination of 17-oxosteroids.

ZINC. [CAS: 7440-66-6]. Chemical element, symbol Zn, at. no. 30, at. wt. 65.38, periodic table group 12, mp 419.58 °C, bp 907 °C, density 7.1 g/cm^3. Elemental zinc has a close-packed hexagonal crystal structure. There are five stable isotopes ^{64}Zn, ^{66}Zn through ^{68}Zn, and ^{70}Zn. Six radioactive isotopes have been identified ^{62}Zn, ^{63}Zn, ^{65}Zn, ^{69}Zn, ^{71}Zn, and ^{72}Zn. With exception of ^{65}Zn which has a half-life of 245 days, the half-lives of the other isotopes are measured in minutes and hours.

Zinc is a bluish-white metal, malleable and ductile at 150 °C, but at 180 °C it changes rapidly so that at 205 °C it may be easily powdered; remains lustrous in dry air but is slightly tarnished in moist air or in water; burns upon heating to vaporization with a bluish flame, forming zinc oxide; soluble in acids — slowly when pure but rapidly on contact with copper or platinum; soluble in alkalies.

Since it is not found free in nature, it was discovered much later than less-reactive metals such as copper, gold, silver, iron, and lead. In early times, the smelting of copper ores containing zinc resulted in brasses, which were known to the Romans before 200 BC. Later, brasses were made by heating copper with zinc oxide or carbonate and charcoal. The oldest piece of zinc extent is an idol found in a prehistoric Dacian site in Transylvania which analyzed at 87.52% zinc, 11.41% lead, and 1.07% iron. Zinc smelting is thought to have originated in China, where it was known in the seventh century AD how to make malleable zinc. In India, zinc was produced from ore mined at Zawar before 1380. By the seventeenth century, zinc was imported into Europe from Asia and in 1743 a zinc smelter for zinc oxide ore was erected in Bristol, UK. By the early nineteenth century, zinc smelting was well established in Germany and Belgium. Zinc was first produced in the United States at the arsenal in Washington, D.C., in 1835, and by 1860 The New Jersey Zinc Company had well-established smelting operations at Bethlehem, Pennsylvania.

In 1758 in England, John Champion was granted a patent for making zinc from roasted zinc sulfide, the main ore of zinc. This route is still the principal method of production today. Commercial zinc metallurgy started with batchwise horizontal retorts, which have had many variations, and progressed to continuous vertical-retort processes. Although some of the latter are important today, electrowinning dominates the field, and the Imperial Smelting blast furnace for zinc–lead remains competitive.

The main application of zinc is to protect iron and other metals from corrosion. Zinc in contact with iron and other metals, as a coating or attached anode, corrodes sacrificially and protects the iron. Most commonly, zinc is applied in the molten state, ie, galvanizing, but is also applied either by electrodeposition or by various mechanical procedures using zinc dust or powder. Another important use is in alloys for die casting. These alloys are used extensively because of their high quality and low cost. Brass and bronze products account for the third largest usage.

Zinc ranks 27th in order of abundance of the chemical elements in the earth's crust, an estimated 0.004% content of igneous rocks on an average basis. It is estimated that a cubic mile of seawater contains about 48 tons of zinc. First ionization potential 9.391 eV; second, 17.89 eV. Oxidation potential $Zn \rightarrow Zn^{2+} + 2e^-$, 0.762 V; $Zn + 4OH^- \rightarrow ZnO2^{2-} + 2H_2O + 2e^-$, 1.216 V. Electron configuration $1s^2 2s^2 2p^6 3s^2 3p^{10} 4s^2$. Ionic radius Zn^{+2} 0.75Å. Metallic radius 1.3324$_5$Å. Other physical properties of zinc are described under **Chemical Elements**.

Zinc and lead usually occur together in nature as sulfides. Earlier separation processes involved the fine grinding of the combined sulfides and then treating the particles with chemical reagents to cause one sulfide to be preferentially wetted and thus the two sulfides separated by the froth flotation process. In a first stage, the lead sulfide is floated while the zinc sulfide sinks to the bottom of the tank. In the second stage, the process is reversed and the zinc sulfide is floated. Gangue and other nonmetals collect at the bottom of the tank. The separated sulfides are dewatered to a 6–7% moisture content and are referred to as the zinc concentrate and the lead concentrate.

A major zinc ore is ZnS (sphalerite) [CAS: 1314-98-3] which frequently occurs with the major lead ore PbS [CAS: 1314-87-0] (galena). The lead-zinc ores usually contain recoverable quantities of copper [CAS: 7440-50-8], silver [CAS: 7440-22-4], antimony [CAS: 7440-36-0], and bismuth [CAS: 7440-69-9] as well, Major deposits of this type are worked in Australia, the United States, Canada, Mexico, Peru, the former Yugoslav Republics, and the former Soviet Union. Two other important zinc ores are $ZnCO_3$ (smithsonite) and iron-zinc-manganese oxide (franklinite). Several of these minerals are described under separate alphabetical entries.

Zinc ores are widely distributed throughout the world; 55 zinc minerals are known. However, only those listed in Table 1 are of commercial importance. Of these, sphalerite provides ca 90% of the zinc produced today. Sulfide ores usually occur in the range of 2–12% zinc (average ca 4%) as mined.

TABLE 1. COMMON ZINC MINERALS

Name	Composition	% Zn
Sphalerite[a]	ZnS	67.0
Hemimorphite[b]		54.2
Smithsonite	$ZnCO_3$	52.0
Hydrozincite	$Zn_5(OH)_6(CO_3)_2$	56.0
Zincite	ZnO	80.3
Willemite	Zn_2SiO_4	58.5
Franklinite	$(Zn,Fe,Mn)(Fe,Mn)_2O_4$	15–20

[a] Zinc blend, wurtzite.
[b] Calamine.

The oxygen-containing ores in Table 1 are often found in richer deposits ranging up to 35% zinc, most commonly smithsonite and hemimorphite. They are thought to have originated from sulfide mineralization and are minor sources of zinc. However, in the beginning, the U.S. zinc industry was based on the deposit of franklinite, zincite, and willemite in Sussex County, New Jersey. Zinc deposits are classified as contact metamorphic, irregular and associated fissure fillings, vein, stratabound in metamorphic rocks, stratabound in carbonate rocks, strataform, and deposits formed by supergene enrichment of laterization. Carbonate rocks, eg, limestone and dolomite, are common host-rocks of zinc ore.

Extractive Metallurgy of Zinc[1]

As of the early 1980s, zinc production throughout the world is based almost exclusively on two processes:

1. Electrolytic Process — in which oxidized zinc concentrates are leached in sulfuric acid and then electrolyzed to plate SHG (special high-grade zinc metal) on the cathode and to regenerate the acid on the anode.
2. ISP (Imperial Smelting Process) — a combined lead-zinc process in which oxidized concentrates are reduced with coke in a shaft furnace and the zinc vapor collected in a lead splash condenser.

The older retort and electrothermic processes have largely been replaced because of environmental and economic reasons.

The ISP evolved to fill a very special niche in nonferrous metallurgy because of its capability of treating lead-zinc concentrates which may also contain appreciable amounts of copper. The concentrate is normally oxidized in a sintering machine to produce a feed for the blast furnace where the zinc oxide is reduced with coke. Some effort has been underway to develop a hot briquetting operation to produce a suitable feed without sintering. Other efforts to improve the economic competitiveness of the process include air preheat and the use of an oxygen-enriched blast to reduce coke consumption.

Although the electrolytic zinc process can trace its industrial history back over 60 years, only during the last 15 to 20 years has it become the industry standard, commanding a large portion of the free world's zinc capacity. While the electrolytic zinc process has been varied to meet the demands of the particular feed, the flow sheet always contains the basic steps of roasting, leaching, solution purification, and electrolysis. The zinc concentrate is oxidized with air to produce acid-soluble zinc oxide (calcine), and sulfur dioxide-containing off gas suitable for conversion to acid, as well as byproduct steam. The Vieille-Montagne/Lurgi fluidized bed roaster is the industry standard.

[1] Information for this topic furnished by C.O. Bounds, St. Joe Minerals Corporation, Monaca, Pennsylvania.

The roaster product is leached with spent electrolyte (sulfuric acid) [CAS: 7664-93-9] under near-neutral conditions to dissolve most of the zinc, copper, and cadmium [CAS: 7440-43-9], but little of the iron [CAS: 7439-89-6]. The leach residue solids are releached in hot, strong acid to dissolve more zinc, since it attacks the otherwise insoluble zinc ferrites. The iron which is also dissolved in this second leach is then precipitated as jarosite, goethite, or hematite. The development of these iron precipitation techniques permitted the use of the hot, strong acid leach and an increase in zinc extraction from about 87% to greater than 95%. Simultaneously, the hot acid leach frequently generates a leach residue rich enough in lead and silver to provide significant byproduct value, as well as increased recovery of cadmium and copper.

The neutral solution is purified to remove impurities more noble than zinc, e.g., cadmium, copper, cobalt [CAS: 7440-48-4], nickel [CAS: 7440-02-0], arsenic [CAS: 7440-38-2], antimony [CAS: 7440-36-0], and germanium [CAS: 7440-56-4]. The purification is accomplished by cementation in two or more steps with the addition of zinc dust. Generally, at least one cementation step is conducted at high temperature with arsenic, antimony, or copper-arsenic added. Cadmium is usually recovered in the metallic state and copper, nickel, and cobalt are recovered as sludges if present in sufficient quantities.

Zinc is extracted from the purified solution in cells using lead/silver alloy anodes and aluminum cathodes at a current density of 38–60 amperes/square foot (400–650 amperes/square meter). The product is normally SHG zinc, particularly if strontium carbonate is added and/or lead/silver anodes of greater than 0.596 silver content are used. After deposition of 24 to 72 hours, the cathodes are removed from the cells and the zinc is stripped by automatic machines in modern plants, melted, and cast for market. The move to automated handling of large cathodes was a major factor in lowering the overall labor requirement in producing zinc.

The following technical developments have led to the acceptance of the electrolytic process:

1. Adoption of high-capacity, low-labor fluidized-bed roasters
2. Adoption of continuous schemes for leaching and solution purification, allowing more automation and lower operating costs
3. Improved raw material utilization via hot acid leaching and iron precipitation as previously described
4. Construction of higher-capacity plants with larger equipment
5. Adoption of mechanized cathode handling/stripping with dramatically lower labor demands
6. Improved byproduct recovery via the hot acid leach.

With exception of leach residue (jarosite, goethite, etc.) disposal, the process is environmentally sound.

The electrolytic process is inherently a somewhat energy inefficient (being based on electrical rather than directly on fossil energy) and capital-intensive operation. A return to pyrometallurgical smelting is conceivable if the environmental concerns are addressed and a noncoke (or at least low-coke) process is developed. New hydrometallurgical developments include the near-commercial Sherritt-Gordon pressure leach to eliminate roasting and the generation of sulfur-dioxide-rich gases, and laboratory experiments with chloride-based leaching/electrolysis.

Production. Principal producers of slab zinc include the former U.S.S.R., Japan, Canada, the United States, Germany (West), Australia, Belgium, France, Poland, Italy, Spain, Mexico, and China. The first four countries mentioned account for well over half of the production. Countries with limited production include Finland, the Netherlands, the former Yugoslav Republics, Bulgaria, and North Korea.

Uses of Zinc

Some concept of the major uses for zinc can be gleaned from Table 2. Slab zinc is available in three grades, as specified by the American Society for Testing and Materials (Table 3).

Zinc Coating. Constituting the largest single use of the metal, zinc coating is accomplished mainly by dipping the product in molten zinc or by electroplating (electrogalvanizing). Hot-dip galvanizing employs chiefly the less pure grades of zinc. The life of galvanized material is proportional to the thickness of the coating, and recent developments in both electrogalvanizing and hot-dip galvanizing have been toward application of heavy coatings that will withstand deformation without peeling.

TABLE 2. CONSUMPTION OF SLAB ZINC IN THE UNITED STATES

Application of Zinc	Percent of Total Tonnage Consumed
Galvanizing	40.8
sheet and strip	26.5
wire and wire rope	2.3
tube and pipe	4.1
fittings (tube and pipe)	0.6
tanks and containers	0.3
structural shapes	0.3
Fasteners	0.5
pole-line hardware	0.4
fencing, wire cloth and netting	1.5
other	2.4
In Brass and Bronze	13.8
sheet, strip, and plate	6.6
rod and wire	5.0
tube	0.6
casting and billets	0.2
copper-base ingots	0.6
Other copper-base products	0.8
In Zinc-base Alloys	28.0
die casting alloy	27.4
dies and rod alloy	0.1
slush and sand casting alloy	0.5
Other Uses	17.4
Rolled zinc	2.2
zinc oxide	3.5
other applications	11.7
Total	100.0

TABLE 3. GRADES OF SLAB ZINC

Grade of Zinc	Composition (Percent)			
	Lead (maximum)	Iron (maximum)	Cadmium (maximum)	Zinc (minimum by difference)
Special High Grade	0.003	0.003	0.003	99.990
High Grade	0.03	0.02	0.02	99.90
Prime Western	1.4	0.05	0.20	98.0

Notes: When specified for use in manufacture of rolled zinc or brass, aluminum is held to 0.005% maximum. Tin in Special High Grade zinc is held to 0.001% maximum. Aluminum in Prime Western zinc is held to 0.05% maximum.
Source: American Society for Testing and Materials.

Because of its relatively high electropotential (position in the emf series of metals), zinc can provide electrolytic protection against corrosion of several common metals, notably products made of iron and steel. Advantage of this characteristic also is taken in the use of zinc as the anode material for a number of types of batteries, power packs, and fuel cells. In providing a protective coating over ferrous metals, the attack of corrosive materials on the zinc produces a relatively inert reaction-product film, which deters destruction of the underlying zinc and base metal. When the coating is broken, as may result from mechanical means such as scratching, abrading, etc., the zinc, having a higher electropotential than the ferrous metals, slowly is expended in furnishing the required protective current. Thus, serious corrosion is delayed for a long period, providing long useful life to the zinc-coated products except in the most adverse cases, or where a poor selection of construction materials was initially made.

The most widely used form of zinc coating is effected by hot-dip galvanizing in which steel sheets, coils, structurals, hardware, wire, and other forms are dipped in a bath of molten zinc. The zinc readily adheres to a previously cleaned (pickled and thoroughly washed) iron or steel surface. The thickness of the coating is controlled by manipulating process temperatures, time the underlying metals are in contact with the molten bath, and mechanical means used. Products that are commonly hot-dip galvanized include roofing, siding, transmission towers, highway guardrails, light poles, culverts, and fencing. Other forms of zinc coating

include flame-spraying or metallizing, flake galvanizing, sherardizing or cementation, plasma arc spraying, vacuum metallizing, and also painting with materials that contain zinc pigments.

Electrogalvanizing makes it possible to apply a zinc coating to such products as steel strip, wire, conduits, hardware, etc. in a high-speed fashion through electroplating. One-side zinc coating of steel sheet for automotive applications by electrodeposition is a notable innovation in recent years. One advantage of electroplating is that the products to be coated are not subject to thermal conditions that may alter dimensions and shape. Electrodeposits range in thickness from 0.00015 inch (0.004 millimeter) to 0.001 inch (0.25 millimeter). Sherardizing is accomplished by heating the ferrous materials to be coated at a temperature of about 350 °C in contact with zinc dust in a closed vessel. The resulting coating consists of iron-zinc alloys. It has been found that sherardized coatings match the corrosion resistance of electrogalvanized or hot-dip coatings of equivalent thickness.

Die Castings. The major use of zinc as a structural material is in alloys for pressure die casting. Development of the modern zinc die-casting alloys was directly related to use of Special High Grade zinc, with the addition of particular alloying constituents held within close limits and control of impurities. For die castings it is essential to use this extra pure grade of zinc to ensure extremely low iron, lead, cadmium, and tin contents. It is also necessary to limit these same impurities in the metals added to make the desired zinc alloy composition. Only by such control can zinc die castings be produced that are stable in dimensions and properties.

The impurities lead, cadmium, and tin, if present in castings in amounts greater than the established maximums (0.005% lead; 0.004% cadmium; 0.003% tin), cause subsurface network corrosion. These limits are close to critical values. Iron is held to 0.10% maximum to prevent excessive skimming losses and machining problems.

Zinc alloys are low in cost of metal per casting, are easy to die cast, are cast at low temperatures, have greater strength than all other die-casting metals except the copper alloys, lend themselves to casting within close dimensional limits, permit the thinnest sections yet produced, and are machined at minimum cost. Their resistance to surface corrosion is adequate in a wide range of applications. Prolonged contact with moisture results in formation of white corrosion products, but surface treatments can be applied that largely prevent formation of such products.

Limiting service conditions for standard zinc-base die-casting alloys are as follows: At temperatures slightly above 95 °C (200 °F) their tensile strength is reduced 30% and their hardness 40%. At subzero temperatures, some embrittlement occurs, but impact strength is still in the same range as that of aluminum and magnesium die-casting alloys at normal service temperatures. At room temperature, impact strength of zinc die castings is much higher than that of aluminum or magnesium die castings or iron sand castings.

All die castings have at least a light flash at the die parting, and those requiring movable cores will have some flash around the cores. Flash is also formed around ejector pins at the points at which they make contact with the casting.

Although it often is cheaper to cut threads than to cast them, for many pieces cast threads usually are more economical. Male threads usually are made with a parting parallel to the axis; this leaves a flash at the parting. The flash can be removed with a shaving tool in some instances, but in others a chasing operation is necessary.

Zinc die castings are invariably cast within quite close dimensional limits, but some machining is commonly required in addition to removal of flash, even though it may consist only of such simple operations as punching, drilling reaming, or tapping of holes. Zinc die castings can be soldered or welded, but ordinarily neither technique is used except for special applications or repair.

Many of the finishes applied to other types of metal products can also be applied to zinc die castings, although some differences in formulation as well as occasional differences in method of application may be desirable. The types of finishes applicable to zinc die castings include: mechanical finishes (buffed, polished, brushed, and tumbled); electrodeposited finishes (copper, nickel, chromium, brass, silver, and black nickel); chemical finishes (chromate, phosphate, molybdate and black nickel); and organic finishes (enamel, lacquer, paint and varnish, and plastic finishes). Electrodeposited coatings of virtually any metal capable of electrodeposition can be applied to zinc die castings.

The automotive industry uses by far the largest number of zinc alloy die castings. Zinc makes the average automobile last longer — 17 pounds of zinc protect it from rust. Another 20 pounds are used to make zinc die cast parts like door handles, locks, carburetors, bodies for fuel pumps, windshield-wiper parts, speedometer frames, grilles, horns, heaters, parts for hydraulic brakes, and each tire contains about 1/2 pound of zinc, which is needed to cure rubber. The electrical industry probably uses a larger diversity of die castings than the automotive industry. Such parts are used in washing machines, oil burners, stokers, motor housings, vacuum cleaners, electric clocks, and kitchen equipment and utensils. Zinc die castings are used in business machines — typewriters, recording machines, picture projectors, vending machines, accounting machines, cash registers, cameras, slicing machines, garbage disposers, gasoline pumps, hoists, and drink mixers. Building hardware, padlocks, toys, and novelties also consume a substantial percentage of the total production of zinc-base die castings.

It is interesting to note that Gutenberg (1440s) used metal-based inks in printing the early Bibles. Zinc was used, along with copper and lead. These inks replaced those made of soot, which were prone to evanescence.

Much more detail on zinc metal products and applications will be found in the Horvick (1979) reference listed. Zinc alloys with copper are described under **Copper**.

Chemistry and Compounds. In virtually all of its compounds zinc exhibits the +2 oxidation phase, although compounds of zinc(I) have been reported in the gaseous phase. Zinc is readily oxidized in the presence of hydroxide ions, e.g., by H_2O, this behavior being attributed to the stability of the $Zn(OH)_4^{2-}$ ion. Like other transition group 2 elements zinc has a marked tendency to form covalent structures, e.g., ZnO and ZnS.

Zinc oxide, formed by oxidation of the metal, dissolves in acids to yield Zn^{2+} ions, and in alkalies to form $Zr(OH)_4^{2-}$ ions. It reacts slowly with moist CO_2 to form the oxycarbonate, $5ZnO \cdot 2CO_2 \cdot 4H_2O$. Addition of an alkali metal hydroxide to a solution of a zinc salt does not precipitate the hydroxide, producing instead hydroxyzincate salt or a precipitate of flocculant zinc oxide. However, the hydroxide can be obtained from a sodium zincate solution on dilution and standing. Zinc hydroxide is amphiprotic, yielding Zn^{2+} ions with acids and $Zn(OH)_4^{2-}$ ions with (excess of) alkali hydroxides. Zinc peroxide is produced by treating a zinc chloride solution with sodium peroxide at a pH of 9.5. It is unstable, decomposing slowly on standing. Zinc oxide is used extensively in rubber, paints, and chemicals. Expanding uses include exterior latex paints, particularly alkyd-modified latex, the photocopy paper field, and as a substitute for mercury in mildew and fungus prevention formulations.

Unlike the other zinc halides, zinc fluoride, ZnF_2, is only slightly soluble in cold water. The anhydrous halides are prepared by direct union of the elements. In solution, zinc chloride, bromide, and iodide exhibit anomalous conductance properties attributed to undissociated molecules and complex ions. On heating these solutions, halogen acids, HX, are evolved, leaving oxyhalides in the fused residue. The zinc halides readily form double salts with halides of elements of main groups 1, 2, and sometimes 3 and 4. See also **Bromine**.

Zinc oxycarbonate is formed by the reaction of suspensions of the oxide or hydroxide with CO_2; to produce the normal carbonate, a very rapid stream of carbon dioxide and, usually, a somewhat higher pH is required.

Zinc also forms both nitrates and oxynitrates (in various hydrated forms) but the oxynitrate is less stable. It is formed by heating the hexanitrate, or treating the nitrate solution with NH_3.

Zinc forms a wide variety of other salts, many by reaction with the acids, though some can only be obtained by fusing the oxides together. The salts include arsenates (ortho, pyro, and meta), the borate, bromate, chlorate, chlorite, various chromates, cyanide, iodate, various periodates, permanganate, phosphates (ortho, pyro, meta, various double phosphates), the selenate, selenites, various silicates, fluosilicate, sulfate, sulfite, and thiocyanate.

Zinc sulfide, selenide, and telluride are more pronouncedly covalent than the oxide. They can be prepared from the elements, or in the case of first two, by the action of H_2S or hydrogen selenide upon zinc solutions. Zinc nitride, Zn_3N_2, prepared from zinc dust and NH_3, hydrolyzes readily to NH_3 and the oxide. Two zinc phosphides are known; Zn_3P_2, formed by

heating the elements, yields phosphine with acids; ZnP_2 and ZnHP have also been prepared.

One of the features of the chemistry of zinc is the fact that it is among the elements having a large number of complex compounds, mostly with coordination numbers of four and tetrahedral, but some with coordination numbers of 6, such as those of ethylenediamine which contain the ion $[Zn(en)_3]_{2+}$. The large number of halogen double salts have already been cited. The marked donor ability of oxygen toward zinc is evident from the number of basic salts, the existence of the zincates (containing ZnO_2^{2-} and also $Zn(OH)_4^{2-}$, the latter in strong alkali), and the formation of such chelate complexes as acetylacetonates and dioxalato complexes. Sulfur is a better donor than oxygen, so that addition compounds of the type $(R_2S)_2ZnX_2$ are formed from dialkyl sulfides and zinc halides, while thiourea forms chelate complexes containing $[Zn(th)^2]^{2+}$. The ready reactions with ammonia, as with amines, give large numbers of complexes; those with ammonia include diammines, triammines and tetrammines, containing $[Zn(NH_3)_2]^{2+}$, $[Zn(NH_3)_3]^{2+}$ and $[Zn(NH_3)_4]^{2+}$ respectively.

Prominent among the carbon donor complexes are the cyanides, principally compounds of $[Zn(CN)_4]^{2-}$, although $[Zn(CN)_3]^-$ is also known. Other carbon donor complexes are the triethyl and tetraethyl complexes, which are readily electrolyzed.

Health and Safety Factors; Environmental Aspects

The level of natural versus man-made emissions to the environment are of a similar magnitude. Soil erosion is the major contributor of natural emissions with zinc mining, zinc production facilities, iron and steel production, corrosion of galvanized structures, coal and fuel combustion, waste disposal and incineration, and the use of zinc fertilizers and pesticides being the principal anthropogenic contributors.

The concentrations of zinc in air, water, and soil are highly variable depending on geological considerations and the influences of point sources in the area. The natural background concentrations of total zinc range from $<0.1-50$ μg/L in fresh water, $0.002-0.1$ μg/L in seawater, $10-300$ mg/kg dry weight in soil, and up to 300 ng/m^3 in air.

Zinc is an essential element and thus can exist in both the deficient or toxic state in plants and animals. Deficiency occurs in some plants when the tissue content drops below 20 ppm. The normal range is $25-150$ ppm. The toxic effect of zinc has been seen at 400 ppm, although plants vary widely in their tolerance.

Direct application of zinc to soil to optimize growing conditions is accomplished using commercial-type fertilizers or through the application of municipal sewage sludge. The latter is closely regulated in order to prevent metals, including zinc, from accumulating to levels that would become phytotoxic or result in an undue exposure to humans through the ingestion of food or soil.

Like plants, marine and fresh water organisms vary significantly in their response to zinc. The range of concentration among species is relatively narrow, except for oysters, which tend to accumulate zinc to very high levels. The zinc content of most seafoods ranges from $3-30$ ppm. Oysters contain from $100-2000$ ppm.

Zinc is also an essential food element in the human diet. Too little zinc in the diet can lead to poor health, reproductive problems and a lowered ability to resist disease. Taking too much zinc into the body through food, water or dietary supplements can also affect health. The levels of zinc that produce adverse effects are higher than the Recommended Daily Allowances, which are 15 mg/day for men, 12 mg/day for women, 10 mg/day for children and 5 mg/day for infants.

Hazards of Production. In most zinc mines, zinc is present as the sulfide and coexists with other minerals, especially lead, copper, and cadmium. Therefore, the escape of zinc from mines and mills is accompanied by these other often more toxic materials. Mining and concentrating, usually by flotations, does not present any unusual hazards to personnel. Atmospheric pollution is of little consequence at mine sites, but considerable effort is required to flocculate and settle fine ore particles, which would find their way into receiving waters.

Drainage from active mining areas is considerably less than from inactive mines because of the disposal methods currently employed. Prior to discharge, liquid effluents are limed and settled to precipitate metals as hydroxides. Flocculants are used to reduce the total suspended solids and, in some instances, filtration of thickener overflow is practiced.

Particulate emissions are controlled mainly through venting, baghouses and water scrubbers. Atmospheric zinc loss is estimated at 100 g/t or zinc mines, mostly from handling dry ore and concentrate and wind erosion of tailing piles. Sulfur dioxide emissions have been reduced by installing double absorption acid plants and improved containment of dilute gases.

The most significant occupational exposures to zinc would occur during the smelting and refining of zinc ore. The standards for occupational exposure have been established at a level to prevent the onset of metal fume fever. This temporary condition is caused by excessive exposure to freshly formed fumes of zinc oxide and results in flulike symptoms of fever, chills, headache, muscle pain, nausea and vomiting.

ZINC FINGERS. The term *zinc finger* is widely used to describe small (typically less than 100–amino acid residues) protein domains that contain a Zn(II) ion chelated by four cysteine or histidine (or occasionally glutamate or aspartate) side chains. This metal chelation strategy constitutes an effective means of stabilizing small protein domains, especially inside the cell in which the reducing environment precludes the formation of disulfide bonds. Zinc fingers are traditionally classified

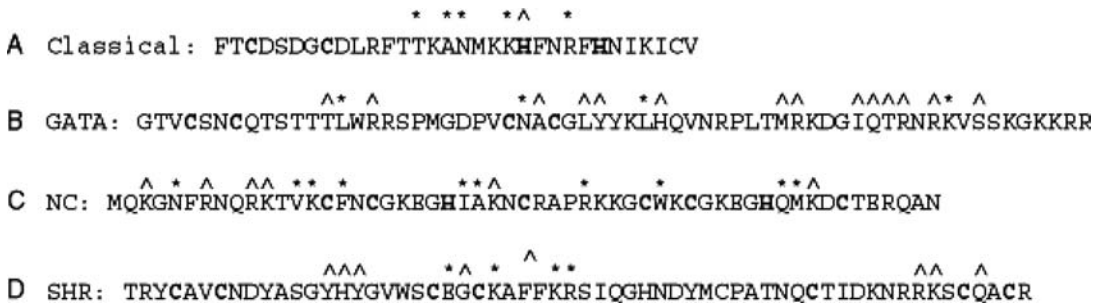

Fig. 1. The amino acid sequences and DNA contact residues for members of four classes of DNA-binding zinc fingers. Residues that contact DNA bases and the sugar-phosphate backbone are indicated with * and ∧, respectively. Residues that coordinate zinc are shown in bold. (**a**) The third finger of TFIIIA. (**b**) The C-terminal finger of GATA-1. (**c**) The nucleocapsid protein from HIV-1. (**d**) Two fingers of the estrogen receptor, a member of the steroid hormone receptor superfamily.

on the basis of either the residues through which they coordinate zinc or their overall structure. The three best-characterized classes are the classical (CCHH) fingers, the GATA-type (CCCC) fingers, and the steroid receptor family (CCCC) fingers (Fig. 1), but other zinc-binding modules such as nucleocapsid fingers, PHD fingers, RING fingers, FYVE fingers, LIM domains, and zinc bundles are also known. Zinc fingers were initially recognized as protein structures that mediate contact with DNA and RNA, but more recently it has become apparent that zinc-binding modules also serve as protein-interaction or lipid-binding domains. Many proteins contain multiple zinc finger domains and in most cases more than one zinc finger is required for high-affinity sequence-specific DNA recognition. Some proteins contain large arrays of more than 30 zinc fingers but the precise function of these proteins remains to be elucidated. Zinc fingers are of medical importance for several reasons: first many zinc finger proteins are essential regulatory factors and mutations that impair their function cause human diseases; second our knowledge of these domains is such that it is possible to design novel zinc fingers with desired DNA-binding specificity that may serve to control gene expression for therapeutic purposes; and third certain zinc-binding modules are essential to the reproduction of viral pathogens and parasites and therefore represent a potentially attractive target for pharmaceutical agents. See also **Zinc (In Biological Systems)**.

ZINC (In Biological Systems). Zinc was one of the first of the trace elements known to be essential for both plants and animals, and yet problems of zinc nutrition are still of pressing importance. Evidence of zinc deficiency in crops is being recognized in new areas and the use of zinc in fertilizers has increased steadily in recent years. A dry, cracked condition of the skin of pigs (*parakeratosis*) caused by a zinc-deficiency has been a problem to pork producers. Diseases and syndromes that have been attributed to zinc deficiency in the human diet include loss of appetite, loss of sense of taste, and delayed healing of burns and other wounds. It is interesting to note that application of zinc-containing ointments to promote healing is an old practice in human medicine. Laboratory animals deficient of zinc may be subject to serious reproductive problems, including infertility of males, failure of conception or implantation of the embryo, difficult births, and deformed offspring. The extent to which zinc deficiency is a primary cause of reproductive problems in farm animals and humans is not thoroughly understood, and research continues.

Patients of both sexes with sickle cell anemia have been reported to be zinc deficient. Administration of zinc to males with this disease has been shown to improve the hypogonadism and the short stature associated with this deficiency. Administration of small dosages of zinc sulfate is part of the therapy in treating certain types of sickle cell anemia. See also **Anemias**.

Zinc deficiency in crops is frequently observed where fields have been graded to smooth them so that irrigation water can be applied more uniformly. Where the topsoil is cut away from small areas of these fields, such crops as corn (maize) and beans may be stunted and many leaves will be white instead of the usual green. If zinc fertilizers, supplying as little as 10 pounds of zinc per acre (11.2 kilograms per hectare) are applied, bumper crops may be grown on these soils. Citrus trees are commonly fertilized with zinc.

When zinc fertilizers are used on soils deficient in zinc, crop production may be increased even though the zinc concentration in the plant tissues and especially in the seed show no increase. With higher levels of zinc fertilization, the zinc concentration in plants may increase. Some evidence shows that the value of food and feed crops as sources of dietary zinc can be improved by using zinc fertilizers at rates exceeding those required for optimal plant growth. However, very high rates of zinc fertilization can depress crop yields.

The zinc contained in plants is not fully utilized by animals. Diets high in calcium and phosphorus have been associated with poor digestibility of dietary zinc. Diets with large amounts of soy protein are particularly likely to require extra zinc fortification for livestock. Meat is an important source of zinc for human diets. Where supplementation of zinc is indicated, zinc sulfate, zinc oxide, and zinc carbonate are commonly used.

Zinc in Metabolism. Zinc was first recognized as a trace element — then referred to as a growth factor for Aspergillus niger — by Raulin (1869). Evidence for a specific biochemical role of zinc was first obtained by Keilin and Mann in 1940, when the metal was shown to be a stoichiometric component of bovine carbonic anhydrases. The findings of many other zinc-containing enzymes during the interim have indicated a diverse biological role for zinc.

The high affinity of zinc for nitrogenous and sulfur-containing ligands seems chiefly responsible for the occurrence of zinc in a wide variety of biological compounds, such as proteins, amino acids, nucleic acids, and porphyrins. Operationally, the enzymes affected by zinc can be considered in two groups: (1) zinc metalloenzymes; and (2) zinc metal-enzyme complexes. Zinc metalloenzymes incorporate zinc so firmly in the protein matrix that they can generally be considered as an entity. Under reasonably mild conditions, the metal and protein moiety are isolated together and exhibit an integral stoichiometric relationship. On the same basis, a strict correlation is preserved between metal and enzyme activity, allowing the inferential identification of a specific biological function of zinc in vivo. Zinc metal-enzyme complexes, in contrast, comprise enzymes which are activated in vitro by the addition of zinc ions. The loose association and the relative lack of metal ion specificity render it difficult in many cases to assign specific biological significance to zinc in vivo.

In zinc metalloenzymes, zinc is a selective stoichiometric constituent and is essential for catalytic activity. It is frequently present in numerical correspondence with the number of active enzymatic sites, coenzyme binding sites, or enzyme subunits. Removal of zinc results in loss of activity. Inhibition by metal complexing agents is a characteristic feature of zinc metalloenzymes. However, no direct relationship holds between the inhibitory effectiveness of these agents and their affinity for ionic zinc. Although zinc is the only constituent of zinc metalloenzymes in vivo, it can be replaced by other metals in vitro, such as cobalt, nickel, iron, manganese, cadmium, mercury, and lead, as in the case of carboxypeptidases.

Zinc is a ubiquitous component of animal and plant tissue. In vertebrates, most organs, including pancreas, contain 20–30 micrograms of zinc per gram of wet tissue. Liver, voluntary muscle, and bone hold about double this amount. Zinc contents ranging from 100 to 1000 micrograms/gram weight have been measured in islet tissues of certain teleost fishes. Correlation between zinc content and insulin storage suggest a parallelism, but evidence is wanting for zinc-insulin complexes in vivo. The highest

zinc content determined among mammals is found in the *tapetium lucidum cellulosum* of adult for seals — up to 150,000 micrograms/gram. Human blood contains 7–8 micrograms zinc/milliliter. About 12% of this is present in serum, 3% in leukocytes, and 85% in erythrocytes. In these compartments, zinc occurs as part of zinc proteins and zinc metalloenzymes. In erythrocytes, zinc is correlated to carbonic anhydrase activity.

In 1991, B.C. Cunningham, M.J. Mulkerrin, and J.A. Wells (Genetech) reported that size-exclusion chromatography and sedimentation equilibrium studies demonstrated that zinc ion (Zn^{2+}) induced the dimerization of human growth hormone (HGH). Scatchard analysis of $^{65}An^{2+}$ binding to HGH shows that two Zn^{2+} ions are associated per dimer of HGH in a cooperative fashion. Cobalt (II) can substitute for Zn^{2+} in the hormone dimer and gives a visible spectrum characteristic of cobalt coordinated in a tetrahedral fashion by oxygen- and nitrogen-containing ligands. Human growth hormone is synthesized and secreted into storage granules before its release from the anterior pituitary.

In 1991, R.E. Klevit (University of Washington) reported on the recognition of DNA by Cys_2, His_2 zinc fingers. The "zinc finger" protein motif was so named because of the tandemly repeating pattern observed in the amino acid sequence of the transcription factor TFIIA. Klevit points out, "According to the original hypothesis, each 30-residue sequence is an independently folded unit that binds a zinc ion and is responsible for sequence-specific DNA binding." See also **Zinc Fingers**.

Underwood (1977) reported that high levels of dietary zinc interfere with the normal absorption and metabolism of several minerals. Earlier, Stewart and Magee (1964) reported that experience with laboratory animals indicated that 7500 parts per million (ppm) zinc in a purified diet lowered the concentrations of calcium and phosphorus in bone. Other investigators showed that animals fed the same level of zinc were anemic and had deformed, fragile erythrocytes. The livers contained reduced amounts of ferritin and lower concentrations of iron in the ferritin. Whanger and Weswig[1971] showed that in rats fed 2000 and 4000 ppm zinc, liver copper concentration was decreased. The most sensitive responses to zinc have been obtained with animals receiving minimally required or suboptimal levels of copper Campbell and Mills, 1974; and Murthy et al., 1974). Based upon these earlier findings, Hamilton et al.[1979] investigated possible zinc interference with copper, iron, and manganese in young Japanese quail (*Coturnix coturnix japonica*). The objective of the investigators was to identify the minimal level of excess dietary zinc that would produce physiological and metabolic deviations from normal and to define some of the most sensitive zinc-mineral interactions. Because other workers had found a sensitive zinc-copper antagonism, the Hamilton team studied the effects of supplemental zinc at copper levels of marginal deficiency. Data from the study showed that adequacy of copper intake is important when supplemental zinc is consumed either as a dietary supplement or in foods fortified with zinc. It was reported that results of the findings may be important for the general human population, whose dietary intake of many minerals, including copper, does not usually exceed the requirement or may be marginally deficient (Milne et al., 1978; Harland et al., 1978; Klevay, 1978). See also **Copper (In Biological Systems)**.

Zinc Poisoning: Soluble zinc salts are usually the etiologic agent in cases of zinc poisoning. The poisonous nature of zinc may be described as astringent, corrosive, and emetic. Sources of food poisoning include zinc-coated galvanized containers, pots, cans, tubs, and acids that convert zinc into soluble salts. Products that may be so involved include lemonade, cooked apples, mashed potatoes, spinach, chicken and tomatoes, and fruit punch. Zinc in combination with various organic and inorganic radicals (dimethyl dithiocarbamate, arsenate, etc.) can be quite poisonous.

ZINCITE. This mineral, (Zn, Mn)O, is an ore of zinc and occurs in considerable quantities at Franklin Furnace, New Jersey, where it is associated with willemite and franklinite. Its hexagonal crystals are rare, as it usually occurs massive, foliated, or in coarse to fine grains. When the crystals are observable, it reveals a perfect cleavage parallel to the base of the prism. The fracture is conchoidal. The mineral has a hardness of 4; specific gravity, 5.684; luster, subadamantine to vitreous; orange-yellow streak; color, red to orange-yellow; translucent to opaque. Zincite also has been found in Poland, Tuscany, Spain, Saxony, and Tasmania.

ZINC TRANSPORTERS. The identification of human zinc deficiency in the 1960s provided a firm basis for the importance of an adequate zinc supply for humans. A variety of symptoms, particularly those related to immunity dysfunction, occur when this micronutrient is not provided in amounts necessary to support its catalytic, structural, and regulatory roles (1). To meet zinc needs, the gastrointestinal tract homeostatically regulates absorption through both intestinal uptake and endogenous secretion (2). Transport rates are adjusted to produce such changes.

A collective body of evidence suggests that zinc transport in mammalian cells is not energy-dependent. Transport kinetics are saturable, sulfhydryl and pH-dependent, and are influenced by ligands, for example, albumin that present zinc and competing metals to cells. The tendency of zinc to bind nonspecifically to extracellular sites and perhaps intracellular sites also needs to be considered in the interpretation of zinc transport in cell or intact animal experiments. These principles need to be considered when relating physiological relevance to zinc transporter gene identification. Furthermore, the direct involvement in actual transport has yet to be definitively established for most zinc transporters, and some information on putative transporters is only based on structural similarity of the genes and proteins involved. Involvement of ionic exchange and cotransport are

also unresolved issues in understanding zinc trafficking and the role of individual transporters.

Much of the early data on zinc transporter genes and those for other metals were acquired in microorganisms, particularly yeast and *Escherichia coli*, and later in plants, for example, *Arabidopsis*. Many of these genes were initially identified through their ability to impart resistance to zinc at times of stress, produced by high zinc concentrations. This approach was used to clone the first mammalian zinc transporter. There are now two major families of mammalian zinc transporters, the ZnT and the ZIP families.

ZINGG PEBBLE CLASSIFICATION. In 1905, Theodor Zingg (Switzerland) proposed a classification of pebble shapes, based upon the graphical representation of the diameter ratio of intermediate (width) to maximum (length) plotted against the diameter ratio of minimum (thickness) to intermediate dimensions. Four classes are specified: spheroid; disk; blade; and rod.

ZIP FILE FORMAT. See **Data Compression**.

ZIPF'S LAW. In statistics, a law that seems to be observed in various kinds of empirical data, connecting the size of aggregates with their rank order, according to size. For example, if the towns in a given country are ranked according to population x, beginning with the largest, it is often found that the rank r is connected with x by a relation of the type $r = k/x^p$ where k and p are constants. A special case occurs when $p = 1$, in which event the product of r and x is a constant. Laws of a similar but rather more complicated kind have been studied in such different fields as the distribution of businesses, of authors by number of publications, and of fragmentation in bombs.

ZIRCON. This mineral is zirconium silicate [CAS: 10101-52-7], $ZrSiO_4$, and is the chief ore of zirconium [CAS: 7440-67-7]. Zircon occurs in square tetragonal prisms, although sometimes it assumes pyramidal or irregular forms. The mineral may be found in some beach and river placer deposits, but generally it is associated as an accessory mineral in siliceous igneous rocks, crystalline limestones, schists, and gneisses — and in sedimentary rocks derived from the foregoing. Zircon is without good cleavage; is brittle, with a conchoidal fracture; hardness, 7.5; specific gravity, 4.6–4.7; luster, adamantine, brilliant; color, green, yellow-green, golden-yellow, red, red-brown, brown, blue, black, and colorless. The name zircon derives from an Arabic word *zarqun*, meaning vermilion, or perhaps from the old Persian *zargun*, meaning golden-colored.

Zircons reputation has suffered of late due to the introduction of a diamond simulant. So for the record, zircon is **NOT** the same material as the artificial gem material **Cubic Zirconia** (or CZ). However with that in mind, zircon has been used as a diamond simulant both for innocent and nefarious reasons. Zircon resembles diamond in luster and fire and colorless zircons have been mistaken for diamonds by experienced jewelers. Zircon can make a very attractive and affordable gemstone. It is found in browns and greens but can be heat treated to beautiful blue and golden colors. Colorless material is produced in this way as well. Zircon is the December Birthstone. Gem quality crystals from Ceylon (Sri Lanka) have been known for many years.

Zircon occurs in the Ural Mountains; Trentino, Monte Somma, and Vesuvius, Italy; Arendal, Norway; Ceylon, India; Thailand; at the Kimberley mines, Republic of South Africa; Madagascar; and in Canada in Renfrew County, Ontario, and Grenville, Quebec. In the United States, zircon is found at Litchfield, Maine; Chesterfield, Massachusetts; in Essex, Orange, and St. Lawrence Counties, New York; Henderson County, North Carolina; the Pikes Peak district of Colorado; and Llano County, Texas.

Commercially, zircons are mined for the metal zirconium which is used for abrasive and insulating purposes. It is the source of zirconium oxide, one of the most refractory materials known. Crucibles of ZrO are used to fuse platinum at temperatures in excess of 1755 °C (3191 °F). Zirconium metal is used in nuclear reactors due to its neutron absorption properties. Large specimens are appreciated as gemstones, owing to their high refractive index (zircon has a refractive index of around 1.95, diamond around 2.4). The color of zircons that do not have gem quality can be changed by heat treatment. Depending on the amount of heat applied, colorless, blue and golden-yellow zircons can be made.

ZIRCONIUM. [CAS: 7440-67-7]. Chemical element symbol Zr, at. no. 40, at. wt. 91.22, periodic table group 4, mp 1,853 °C, bp 4,376 °C, density 6.44 g/cm^3, 6.47 g/cm^3 (single crystal). Metallic zirconium is allotropic. Up to about 863 °C, the alpha phase (hexagonal close-packed) is stable; above this temperature, the metal assumes the beta phase (body-centered cubic). The most common impurity, oxygen, tends to stabilize the alpha phase.

Zirconium metal exhibits passivity in air due to the formation of adherent coatings of oxide or nitride. Even without the coating, it is resistant to the action of weak acids and acid salts, but dissolves in HCl (warm) or H_2SO_4 slowly, and more rapidly if F is present, forming compounds of ZrO^{2+} ions, or fluorozirconates in the last case.

Crystalline zirconium of high purity is a white, soft, ductile, and malleable metal, but that of 99% purity, when obtained at high temperature, is hard and brittle. Pure zirconium has a combination of properties which make it a valuable structural material for nuclear reactors. In addition to low neutron capture, zirconium has good strength at high temperatures, corrosion resistance to high velocity coolants, avoidance of formation of high activity isotopes, and resistance to mechanical damage from neutron radiation. Amorphous zirconium is a bluish-black powder. At about 500 °C zirconium burns in air; heated in hydrogen forms hydride; heated in nitrogen a nitride; and heated in chlorine the tetrachloride. On the laboratory scale, zirconium metal may be produced by the reduction of the chloride, oxide, or potassium zirconium fluoride with sodium metal.

Zirconium occurs naturally as a silicate in zircon [CAS: 1490-68-2], the oxide baddeleyite [CAS: 12036-23-6], and in other oxide compounds. Zircon is an almost ubiquitous mineral, occurring in granular limestone, gneiss, syenite, granite, sandstone, and many other minerals, albeit in small proportion, so that zircon is widely distributed in the earth's crust. The average concentration of zirconium in the earth's crust is estimated at 220 ppm, about the same abundance as barium (250 ppm) and chromium (200 ppm).

Zircon has been known as a gem mineral since biblical times and was known as jargon in Sri Lanka (Ceylon) and as hyacinth in France. The name zircon possibly comes from the Arabic *zargon* for the gold or dark amber color of the more common gemstone. Zircons may be colorless, amber, red, reddish brown, blue, green, or black. In 1789, Klaproth announced that in analyzing jargon from Sri Lanka he had found 68% of an unknown earth which he called zirkonerde. In 1797, Vauqelin studied this new earth, to which the name zirconia was given, and published the preparation and properties of some of its compounds. In 1824, Berzelius prepared the first crude zirconium metal, a black powder, by heating potassium and potassium hexafluorozirconate [CAS: 16923-95-8] in a closed pot. In 1914, the first relatively pure zirconium was prepared by the reduction of zirconium tetrachloride [CAS: 10026-11-6] with sodium in a bomb.

High purity zirconium was first produced by van Arkel and de Boer in 1925. They vaporized zirconium tetraiodide [CAS: 13986-26-0] into a bulb containing a hot tungsten filament which caused the tetraiodide to dissociate, depositing zirconium on the filament.

Zirconium was first identified by Klaproth in 1789. The first crude powder was made by Berzelius in 1824 by reducing potassium fluorozirconate with potassium. A sample with a purity of 98% was not produced until the 1950s.

There are five natural isotopes ^{90}Zr through ^{92}Zr, ^{94}Zr, and ^{96}Zr. See Table 1. Six radioactive isotopes have been identified ^{87}Zr through ^{89}Zr, ^{93}Zr, ^{95}Zr, and ^{97}Zr. With exception of 93Zr with a half-life of 1.1×10^6 years, the half-lives of the other isotopes are expressed in minutes, hours, or days. Zirconium is ranked 19th in abundance of the

TABLE 1. NATURALLY OCCURRING ZIRCONIUM ISOTOPES

chemical elements occurring in the earth's crust with an estimated average content of zirconium in igneous rocks of 0.026%.

First ionization potential 6.95 eV; second, 13.97 eV; third, 24.00 eV; fourth, 33.83 eV. Oxidation potentials $Zr + 2H_2O \rightarrow ZrO_2 + 4H^+ + 4e^-$, 1.43 V; $Zr + 4OH^- \rightarrow ZrO(OH)_2 + H_2O + 4e^-$, 2.32 V. Electronic configuration $1^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^2 5s^2$. Ionic radius Zr^{+4} 0.80Å. Metallic radius 1.5895Å. Other important physical properties of zirconium are given under **Chemical Elements**.

The most important ore for production of zirconium metal is zircon $ZrSiO_4$, which occurs in several regions in the form of a beach sand, often mixed with silica, ilmenite, and rutile. A floating-dredge technique is used in the mining operation. Early phases of beneficiation often take place on the dredge. Nearly all of the silica is separated by means of spiral concentrators, with the ilmenite and rutile removed by magnetic and electrostatic separators. The purest concentrates are used for metal production; others for refractories. Direct chlorination of the ore is the most modern method of extraction. In a simple reaction, water-soluble zirconium tetrachloride is yielded. Liquid-liquid extraction in several stages is required for the removal of hafnium. With this process, zirconium containing less than 50 ppm hafnium can be produced. Ammonium thiocyanate is used to complex the zirconium while hafnium is extracted by a methyl ethyl ketone solvent. In a similar system, HNO_3 is used in the aqueous phase and tributyl phosphate as the solvent. After separation, the two metals are precipitated as their sulfates or hydroxides. Calcination yields a pure ZrO_2. For production of pure metal, the pure ZrO_2 is chlorinated to $ZrCl_4$. Sometimes this is sublimed for additional purification. The zirconium tetrachloride in the gaseous phase is reacted with molten magnesium, forming zirconium metal and magnesium chloride. There are several minor variations of these processes. For example, sodium may replace magnesium.

Chemistry and Compounds. Due to its $4d^2 5s^2$ electron configuration, zirconium forms tetravalent compounds readily, although the Zr^{4+} ion does not exist as such in aqueous solution, except at very low pH values, the common cation being hydrated ZrO^{2+} (or $Zr(OH)_2{}^{2+}$). Many of the tetravalent compounds are partly covalent. There are also less stable Zr(III) compounds. The remarkably close similarity in chemical properties to those of hafnium [CAS: 7440-58-6] is due to the identical outer electron configuration ($5d^2 6s^2$ for Hf) and the almost identical ionic radii (Hf^{4+} is 0.86Å) this relatively low value for Hf^{4+} being due to the lanthanide contraction.

Zirconium oxide, [CAS: 1314-23-4] ZrO_2 is widely known, both as a mineral, baddeleyite, and as an industrial product obtained from zircon, $ZiSO_4$. Moreover, the precipitate obtained by action of alkali hydroxides upon solutions of tetravalent zirconium is a hydrated oxide. The latter is readily soluble in acids to form oxysalts, which are usually formulated in terms of the ZrO^{2+} ion, without including its water of hydration, e.g., as $ZrO(H_2PO_4)_2$. The hydrated ZrO^{2+} ion is not amphiprotic; it does not dissolve in alkali hydroxides. While it does react on alkali carbonate fusions, the compounds formed have been shown to be mixed oxides rather than zirconates.

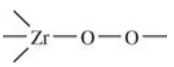
All four of the halides of zirconium and the common halogens are known and are solids at ordinary temperatures. They are readily hydrolyzed, to form hydrated oyxhalides such as $ZrOCl_2 \cdot 8H_2O$ or $ZrOBr_2 \cdot 8H_2O$. The tetraiodide yields both $ZrOI_2 \cdot 8H_2O$ and $ZrI(OH)_3 \cdot 3H_2O$, and this last composition probably represents best the structure of all these compounds. Like titanium tetrahalides, $ZrCl_4$ and $ZrBr_4$ act as Lewis Acids to form adducts, though of lesser stability, with H_2O and oxygen-function compounds, such as alcohols, ethers, and carboxy compounds generally. These include chelates formed with such compounds as 1,2-dihdroxybenzene and acetylacetone [CAS: 123-54-6], in which oxygen atoms act as electron donors. Zirconium also forms very stable complexes with $POCl_3$.

The trihalides of zirconium, like the dihalides of titanium, are extremely strong reducing agents, reacting even with H_2O.

Zirconium nitride [CAS: 25658-42-8], Zr_3N_4, is made by ammoniating the tetrachloride to yield $Zr(NH_3)4Cl_4$, which yields the nitride on heating. The nitride, like the boride and carbide, are alloy-like in character, with high fusing points, extreme hardness, and subject to considerable variation in composition. Thus Zr_3N_4 may vary in composition to ZrN without material change in its properties.

Unlike titanium, zirconium forms a few normal tetravalent salts, such as a tetranitrate and a tetrasulfate, as well as its more common basic salts. However, the normal salts readily undergo hydrolysis to form the basic salts.

Like titanium, zirconium forms halogen complexes, the most stable of which is the hexafluoride, $ZrF_6{}^{2-}$, as well as $ZrCl_6{}^{2-}$, and $ZrBr_6{}^{2-}$, which are less stable, except in concentrated solutions of the hydrogen halides. Zirconium also forms stable peroxy complexes, containing



Unlike titanium, zirconium forms a heptafluoride ion, $ZrF_7{}^{3-}$, which is quite stable.

Zirconium hydride [CAS: 7704-99-6] in powder form was produced by the reduction of zirconium oxide with calcium hydride in a bomb reactor. However, the workup was hazardous and many fires and explosions occurred when the calcium oxide was dissolved with hydrochloric acid to recover the hydride powder. With the ready availability of zirconium metal via the Kroll process, zirconium hydride can be obtained by exothermic absorption of hydrogen by pure zirconium, usually highly porous sponge. The heat of formation is 167.4 J/mol (40 kcal/mol) hydrogen absorbed.

Intermetallic compounds of zirconium with iron, cobalt, and manganese absorb and desorb considerable amounts of hydrogen, up to $ZrMn_{2.4}H_3$ [CAS: 68417-38-9] and $ZrV_2H_{5.3}$ [CAS: 63440-37-9]. These and other zirconium intermetallic compounds are being extensively studied for possible hydrogen storage applications.

The metallic monohalides zirconium chloride [CAS: 14989-34-5], ZrCl, and zirconium bromide [CAS: 31483-18-8], ZrBr, reversibly absorb hydrogen up to a limiting composition of ZrXH. These hydrides are less stable than the binary hydride ZrH_2, and begin to disproportionate above 400 °C (752 °F) to ZrH_2 and ZrX_4 in a hydrogen atmosphere. See also **Hydrides**.

Zirconium carbide [CAS: 12020-14-3], nominally ZrC, is a dark gray brittle solid. It is made typically by a carbothermic reduction of zirconium oxide in a induction-heated vacuum furnace. Alternative production methods, especially for deposition on a substrate, consist of vapor-phase reaction of a volatile zirconium halide, usually $ZrCl_4$, with a hydrocarbon in a hydrogen atmosphere at 900–1400 °C (1652–2552 °F).

Zirconium carbide is inert to most reagents but is dissolved by hydrofluoric acid solutions which also contain nitrate or peroxide ions, and by hot concentrated sulfuric acid. Zirconium carbide reacts exothermically with halogens above 250 °C (482 °F) to form zirconium tetrahalides, and with oxidizers to zirconium dioxide in air above 700 °C (1292 °F). Zirconium carbide forms solid solutions with other transition-metal carbides and most of the transition-metal nitrides without the formation of compounds.

Cubic zirconium nitride, ZrN, a brittle, yellow solid, is prepared by heating zirconium turnings or loose sponge to 1100–1500 °C (2012-2732 °F) in a nitrogen or ammonia atmosphere. The reaction is slow because of the slow diffusion of nitrogen through the protective nitride layer, and nitrogen contents approaching stoichiometric require time or higher temperatures such as those of a plasma torch. Zirconium tetrachloride and nitrogen is a hydrogen atmosphere above 1000 °C (1832 °F) yield zirconium nitride films or powders; impurity effects cause the growth of nitride whiskers. Ammonia and zirconium tetrachloride forms adducts which on heating to 750 °C (1382 °F) give $ZrN_{1.3}$ [CAS: 25658-42-8], which in turn yields ZrN at 1200 °C (2192 °F). Unlike its analogues, TiN and HfN, which are being used as wear-resistant surface

layers on cemented-carbide tool bits, no significant commercial applications for ZrN have been developed.

Zirconium forms two borides: zirconium diboride [CAS: 12045-64-6], ZrB_2, and zirconium dodecaboride [CAS: 12046-91-2], ZrB_{12}. The diboride is synthesized from the elements, by vapor-phase coreduction of zirconium and boron halides, or by the carbothermic reduction of zirconium oxide and boron carbide; boric oxide is avoided because of its relatively high vapor pressure at the reaction temperature.

Zirconium forms several phosphides: ZrP_3 [CAS: 39318-19-9], ZrP_2 [CAS: 12037-80-8], and $ZrP_{0.6}$ [CAS: 12066-61-4]; they are part of the Zr–P phase diagram. The solubility of phosphorus in zirconium metal is low, ca 50 ppm, and at higher concentrations it collects as separate globules at the metal grain boundaries. Analysis indicates that this material is Zr_3P.

The reactions of pure zirconium turnings with threefold quantities of elemental sulfur, selenium, or tellurium give ZrS_3 [CAS: 12166-31-3], $ZrSe_3$ [CAS: 12166-53-9], and $ZrTe_3$ [CAS: 39294-10-5]. Zirconium disulfide [CAS: 12039-15-5] is made from the elemental powders and by the action of carbon disulfide on zirconium oxide above 1200 °C (2192 °F); some ZrOS [CAS: 12164-95-3] is usually also obtained. The higher sulfides disproportionate at ca 700 °C (1292 °F); synthesis reactions at 900–1000 °C (1652–1832 °F) with S:Zr ratios between 0.2 and 2.3 produced crystals that were identified as Zr_9S_2 [CAS: 12595-12-9], $Zr_{21}S_8$ [CAS: 12595-19-6], Zr_2S [CAS: 12334-07-5], ZrS_{1-x}, ZrS [CAS: 12067-18-4], and $ZrS_{1.3}$ [CAS: 37244-09-0]. Zirconium disulfide is a semiconductor with a cadmium–iodide-type layered structure consisting of stacked sandwiches each containing single sheets or metal cations between two sheets of anions.

Several compounds such as $BaZrS_3$ [CAS: 12026-44-7], $SrZrS_3$ [CAS: 12143-75-8], and $CaZrS_3$ [CAS: 59087-48-8], have been made by reacting carbon disulfide with the corresponding zirconate at high temperature, whereas $PbZrS_3$ [CAS: 12510-11-1] was produced from the elements zirconium and sulfur plus lead sulfide sealed in a platinum capsule which was then pressurized and heated. Lithium zirconium disulfide [CAS: 55964-34-6], $LiZrS_2$, was also synthesized. Zirconium disulfide forms organometallic intercalations with a series of low ionization (<6.2 eV)-sandwich compounds with parallel rings.

The dichalcogenides are hexagonal, the diamagnetic trichalcogenides are monoclinic. The compound sulfides $BaZrS_3$ [CAS: 12026-44-7], $SrZrS_3$ [CAS: 12143-75-8], and $CaZrS_3$ [CAS: 59087-48-8] have an orthorhombic distorted perovskite structure, although $BaZrS_3$ prepared at 1000 °C (1832 °F) displayed a tetragonal perovskite structure which was attributed to a sulfur deficiency.

Zirconium dioxide [CAS: 1314-23-4], ZrO_2, is the most important oxide of zirconium. It melts at 2710 ± 35 °C, and in the pure state exists in four solid phases: monoclinic, tetragonal, orthorhombic, and a cubic fluorite structure.

Zirconium oxide is stable to most reagents but dissolves slowly in hot concentrated sulfuric acid and in concentrated hydrofluoric acid. Carbon tetrachloride or phosgene above 300 °C (572 °F), or chlorine and carbon above 600 °C (1112 °F) give $ZrCl_4$. Above 1400 °C (2552 °F), zirconium oxide is reduced by carbon to zirconium carbide. At high temperatures, zirconium oxide reacts with many metal oxides, including BaO, CaO, MgO, SrO, Y_2O_3, Re_2O_3, and PbO, to form solid solution oxides and, with the exception of magnesium, zirconate compounds. Molten-salt synthesis procedures give uniform, stoichiometric, finely divided alkaline-earth zirconate powders for use as a dielectric.

Although lower oxides do not occur terrestrially, they can be produced at high temperature. Zirconium monoxide [CAS: 12036-01-0], ZrO, has been observed in the sun's spectra, and in the spectra of zirconium oxide being evaporated from the surface of a tungsten filament. As oxygen is added to alpha zirconium, additional diffraction lines appear at Zr_3O [CAS: 12059-93-7] and higher oxygen contents; Zr_3O occurs as an ordered super lattice in zirconium, representing the limit of oxygen solubility in zirconium. Other lower oxide compounds that are considered stable are Zr_8O [CAS: 53801-45-9] and Zr_2O [CAS: 12412-49-6].

Zirconium silicate, $ZrSiO_4$, occurs naturally as zircon. Zircon is tetragonal, with the zirconium and silicon linked through oxygen atoms to form edge-sharing alternating SiO_4 tetrahedra and ZrO_8 triangular dodecahedra. Zircon is isomorphous with xenotime which occurs in solid solution in zircon crystals. See also **Zircon**.

Zircon is synthesized by heating a mixture of zirconium oxide and silicon oxide to 1500 °C for several hours. The corresponding hafnium silicate, hafnon, has been synthesized also. Zircon can be dissociated into the respective oxides by heating above 1540 °C and rapidly quenching to prevent recombination. Commercially, this is done by passing closely sized zircon through a streaming arc plasma.

Zircon silicate is highly stable. Decomposition of zircon is accomplished only by very aggressive chemical attack, usually at high temperature.

Many other silicate minerals contain zirconium as a constituent. These minerals may be altered or metamict zircons such as cyrtolite or malacon.

Specifications and Standards

The U.S. specifications for zirconium are listed in Table 2. For nuclear power use, each reactor vendor issues particular, detailed specifications which usually include the pertinent ASTM nuclear specifications.

TABLE 2. U.S. SPECIFICATIONS FOR ZIRCONIUM

Form	ASTM Nuclear	ASTM Commercial	ASME	DOE	AWS[a]
sponge	B 349	B 494			
ingot	B 350	B 495		M 10-1 T	
bars, rod, and wire	B 351	B 550	SB550	M 7-9 T	
flat rolled products	B 352	B 551	SB551	M 5-6 T	
tubing	B 353	B 523	SB523	M 3-8 T	
forging and extrusions		B 493	SB493	M 2-9 T	
bare welding rods			SFA5.24	M 1-16 T	A5.24
descaling and cleaning		B 614			
welding fittings		B 653			
seamless and welded pipe		B 658	SB658		
aqueous corrosion testing	G 2	G 2

Health and Safety Factors. Zirconium is generally nontoxic as an element or in compounds. At pH normally associated with biological activity, zirconium chiefly exists as the dioxide which is insoluble in water and in this form zirconium is physiologically inert.

Chelated complexes such as sodium zirconium lactate [CAS: 15529-67-6] or ammonium zirconium carbonate [CAS: 22829-17-0], and acidic forms such as zirconium hydroxy oxide chloride [CAS: 18428-88-1] have been used in preparations in deodorants or for treatment for poison oak and poison ivy dermatitis. In such occasions, when the skin had been cut or abraded, a few users developed granulomas which have been identified as a delayed hypersensitivity to zirconium. These may take several weeks to develop, and commonly persist for 6 months to over a year.

In massive form, zirconium is commonly brought to red heat before forging, swaging, or other hot working with only slight surface oxidation of the ingot or slab. Conversely, zirconium metal with a high surface area such as sponge, foil, fine powder, fine machining chips, and grinding dust is extremely flammable and often pyrophoric, especially when slightly damp. Many unexpected ignitions have occurred caused by improper handling of finely divided forms of zirconium metal, resulting in more than one incident of fatal flash burns to metal workers. Very fine dusts of zirconium ignite when dispersed in air. Fires can be extinguished with a blanket of argon or a layer of dry salt or sand. Water is hazardous unless the zirconium can be quenched below its ignition temperature. A settled 25-kg mass of 20-μm particles ignited in the bottom of a water-filled 55-gal (208-L) drum burns for hours. A stream of water results in the generation of hydrogen and steam which disperse the burning fragments and spread the fire. Safe handling of zirconium has been discussed in several publications.

Zirconium powder reacts exothermically with many other elements, including hydrogen, boron, carbon, nitrogen, and the halogens, although the ignition temperature is usually above 200 °C (392 °F). The reaction between zirconium powder and platinum is especially violent.

Uses

The largest use is foundry sand, where zircon is used as the basic mold material, as facing material on mold cores, and in ram mixes. Because of

its chemical inertness and high melting point, zircon is wetted less easily by molten metal, producing smoother surfaces on iron, high alloy steel, aluminum, and bronze castings. Zircon-sand molds have greater thermal shock resistance and better dimensional stability than quartz-sand molds. The zircon grains are usually bonded with sodium silicate in the formation of the molds and cores, but other binders, eg, clay, lignin-containing liquors, and furan resin, are used.

Fired zircon and AZS (alumina–zirconia–silica) refractories, including brick, crucibles, and saggers, have their main use in the production of handling of molten glasses. See also **Refractories**. Blends of zircon with alumina or magnesia improve spalling resistance, reduce thermal conductivity, withstand thermal cycling, and have better corrosion resistance in specific glass-furnace environments. Other uses for zircon refractories include hearths and nozzles for handling molten metal and in extrusion dies.

Zirconium oxide is fused with alumina in electric-arc furnaces to make alumina–zirconia abrasive grains for use in grinding wheels, coated-abrasive disks, and belts. See also **Abrasives**. The addition of zirconia improves the shock resistance of brittle alumina and toughens the abrasive. Most of the baddeleyite imported is used for this application, as is zirconia produced by burning zirconium carbide nitride.

Yttria or calcia-stabilized cubic zirconias are used extensively as the solid electrolyte in oxygen sensors in automotive and boiler exhausts, and oxygen-content probes for molten copper or iron in smelters. Stabilized zirconia has been proposed for high temperature fuel cells operating with natural gas, or converting ammonia to nitric acid. Stabilized zirconias are used for diverse applications such as ceramic tubing, extrusion dies, ball-milling media, high temperature heating elements, insulating fibers, thermal barrier coatings, ceramic diesel engines, and a nonlubricated ballbearing assembly for use in a space vehicle. Single-crystal cubic zirconias of high purity are being produced as a substitute for diamonds in jewelry.

Zirconate compounds exhibit several interesting properties. Lead zirconate–titanate [CAS: 12626-81-2] compositions display piezoelectric properties which are utilized in the production of FM-coupled mode filters, resonators in microprocessor clocks, photoflash actuators, phonograph cartridges, gas ignitors, audio tweeters and beepers, and ultrasonic transducers.

The uses of other zirconium compounds result primarily from the ability of zirconium to complex with carboxyl groups and to form an insoluble organic compound. Ammonium zirconium carbonate enhances the fungicidal action of copper salts on cotton cloth and zirconium acetate has been used as an algicide. Both ammonium zirconium carbonate and zirconium acetate [CAS: 14311-93-4] have been used in the waterproofing of fabrics. Freshly prepared zirconium sulfate solutions are preferred over chromium solutions in the tanning of leather to prepare white leathers, although other mixed sulfate solutions containing zirconium, chromium, and aluminum have been proposed. In the retanning of chrome-treated leather, an intermediate treatment with ammonium zirconium carbonate improves the results obtained during the second chrome tanning. See also **Leather**. Zirconium carbonate produces durable acrylic-emulsion floor polishes which are easily stripped by treatment with household ammonia. See also **Polishes**. Both zirconium sulfate [CAS: 14644-61-2] and potassium hexafluorozirconate have been used for flame-resistant treatment of wool fabric. Very dilute fluoride solutions containing zirconium and gluconic acids are used for the preparation of clean aluminum surfaces to be subsequently painted or overcoated. Similarly, an aqueous solution of zirconium nitrate [CAS: 13746-89-9] and poly(vinyl alcohol) is applied as a precoating on glass surfaces before the application of phosphor photobinder in the production of cathode-ray tubes.

Zirconium tetrafluoride [CAS: 7783-64-4] is used in some fluoride-based glasses. These glasses are the first chemically and mechanically stable bulk glasses to have continuous high transparency from the near uv to the mid-ir (0.3–6 μm). Zirconium oxide and tetrachloride have use as catalysts, and zirconium sulfate is used in preparing a nickel catalyst for the hydrogenation of vegetable oil. Zirconium 2-ethylhexanoate [CAS: 22464-99-9] is used with cobalt driers to replace lead compounds as driers in oil-based and alkyd paints.

Because of its flammability, zirconium is used in military ordnance including percussion-primer compositions, delay fuses, tracers, and pyrophoric shrapnel, in getters for vacuum tubes, inert-gas glove boxes, and sodium-filled hollow-shaft exhaust valves, and as shredded foil in flashbulbs for photography and excitation of lasers. Alloying applications of pure zirconium include zirconium–niobium superconductors, titanium aircraft alloys, and strengthening of copper alloys. Pure zirconium is being increasingly used as a corrosion-resistant metal in fabricating columns, pumps, pipe, valves, heat exchangers, and tanks for severe chemical environments, particularly sulfuric and hydrochloric acids, except those containing fluorides. In this capacity, it is also used in facilities producing urea, hydrogen peroxide, methyl methacrylate, or acetic acid.

ZIRCONIUM SILICATE. See **Zircon**.

ZODIAC. A belt on the celestial sphere that extends for an angular distance of 9° from either side of the ecliptic. The zodiac is divided into 12 sections, each 30° long, which are known as the signs of the zodiac. These signs indicate the position of the sun for each month in the year and are named for the zodiacal constellations that occupied the signs about 2,000 years ago. Due to precession, the sign of Aries has moved back into the constellation of Pisces, so that the signs and constellation names no longer agree.

Since the planets all lie relatively close to the ecliptic, their paths along the celestial sphere will lie in the zodiac. It is a common practice with makers of almanacs to indicate the positions of the planets by the sign of the zodiac in which they are to be found. See also **Celestial Sphere and Astronomical Triangle**.

ZODIACAL LIGHT. A faint glow that extends along the ecliptic or zodiac from the vicinity of the sun. The zodiacal light is so faint that it is completely masked by moonlight. It may best be observed in the western sky in the spring after the sunset twilight has completely disappeared, in the eastern sky in the fall just before the morning twilight appears, or during a total solar eclipse. It decreases in intensity with distance from the sun, but on very dark and clear nights, it has been followed completely around the ecliptic. In fact, the work of van Rhijn at the Mount Wilson Observatory indicates that the illumination is not confined to the ecliptic, but presumably covers the entire sky, being responsible for about 60% of the total skylight on a moonless night. There is a slightly increased illumination of the zodiacal light on the ecliptic directly opposite the sun known as the gegenschein.

Photographic observations of the spectrum of the zodiacal light indicate that it is composed of reflected sunlight and is essentially an extension of the F corona. The amount of material necessary to produce the intensity of the light is amazingly small. Calculation indicates that the zodiacal light

could be accounted for if, inside the orbit of the Earth, there were particles 1 millimeter in diameter of the reflecting power of the moon, and each one 5 miles from its neighbors.

Observational studies indicate that the material producing the zodiacal light is located in a lens-shaped volume of space centered on the sun and extending well beyond the orbit of the Earth. Each individual particle, unless small enough to be held away from the sun by radiation pressure, must be moving about the sun in its individual orbit. The intensification of the reflected light at the point directly opposite the sun might be explained either by a concentration of the reflecting particles in this region, or by the fact that directly opposite the sun the particles would be in full phase.

Measurements over a 4-year period from the satellite OSO-5 have failed to show any temporal variations in the surface brightness and polarization of zodiacal light. These observations have tended to cast doubt on prior observations, from rockets and balloons, to the effect that variations in the light do exist, as for example that the brightness of the south pole exceeded that of the north pole by about 15% (at time of observation). Satellite observations have not indicated any north-south asymmetry. The situation is reviewed in more detail by Sparrow and Ney in *Science*, **181** (4098), 438–440 (1973).

ZOISITE. This mineral is a calcium aluminum silicate hydroxide [CAS: 1335-30-4] corresponding to the formula $Ca_2Al_3(Si_3O_{12})(OH)$, crystallizing in the orthorhombic system. Clinozoisite (monoclinic) is its isomorphous counterpart. Named after Austrian scientist Baron Sigmund Zois von Edelstein (Baron von Zois), whom discovered the mineral in the Sau-Alp mountains of Austria in 1805. Zoisite was first known as saualpite, after its type locality. Zoisite occurs as prismatic crystals, usually deeply striated vertically, and as compact or columnar masses. Perfect prismatic cleavage; brittle; uneven to conchoidal fracture; hardness, 6–7; specific gravity, 3.355; luster, vitreous to pearly; transparent to translucent; color, grayish white, green, pink (the manganese-rich variety, thulite), and blue to purple (tanzanite).

Zoisite occurs in crystalline schists which are products of regional metamorphism of basic igneous rocks rich in plagioclase, the calcium-rich feldspar; also in argillaceous calcareous sandstones, thulite from quartz veins, pegmatites, and metamorphosed impure limestones and dolomites.

Zoisite has been known for nearly two centuries as a sometimes ornamental stone of limited distribution. Only in 1967 was the blue gemstone variety found in Tanzania. The variety was named Tanzanite and was a surprise to minerologists and gemologists alike in that it had come from a very ungemstone-like mineral. The blue-lavender color of tanzanite is unique and sets it apart from the other gemstones.

Besides tanzanite, zoisite has produced other attractive specimens that are of interest to collectors. A pink variety called *thulite* is usually massive and used for beads and cabochons. A brilliant green variety is associated with medium grade rubies and is quite popular as an ornamental stone. The red rubies are often distorted and irregularly spread throughout the sea of massive green zoisite. It is one of the most colorful of ornamental stones and competes well with the popular pink tourmaline and lavender lepidolite of California.

ZOLLINGER-ELLISON SYNDROME. A tumor involving the D-cells of the islets of Langerhans is called the D-Cell adenoma. This tumor causes a condition known as the Zollinger-Ellison syndrome. In this syndrome, the D-cells secrete an excessive amount of gastrin. This, in turn, stimulates the parietal cells of the stomach, to produce an increased volume of gastric juices. The gastric hyperactivity can lead to severe peptic ulcer sometimes accompanied by excessive diarrhea. The D-cell adenoma may be either benign or malignant, but requires removal to relieve the symptoms. The presence of a D-cell adenoma also causes an increase in insulin secretion by the beta cells.

ZONAL. See **Meteorology**.

ZONAL ABERRATION. Spherical or monochromatic aberration of a lens of wide aperture due to the fact that the refracting power is different for different zones concentric at the axis.

ZONAL FLOW. See **Atmosphere (Earth)**.

ZONDA. See **Winds and Air Movement**.

ZOND LUNAR MISSIONS. See **Lunar Exploration**; and **Moon Exploration Missions (By the USSR)**.

ZONE. A variously defined term, depending upon scientific field of use. A geographical zone is an area or region of latitudinal character, typically set off from surrounding areas by some distinctive characteristic. For example, the torrid zone, the two temperate zones, and the two frigid zones of the Earth are belts divided with respect to latitude and temperature. A geological zone is a regular or irregular belt, or a layer, band, or strip of earth materials, disposed horizontally, vertically, concentrically, or otherwise, thus providing a distinction from surrounding parts other than nature of content. Specific types of geological zones are a "zone of saturation," a "structural zone," or a "zone of fracture." An ecological zone is a biogeographic region typified by uniform climatic conditions, fauna, and flora; or a zone characterized by the dominance of a particular organism. A biostratigraphic zone is a belt of strata identified paleontologically, irrespective of thickness or lithology. Stratigraphic zone also is a generally used term for a stratigraphic unit of any kind, especially any rock stratum or body of strata which it is useful to recognize as a unit because of its being characterized by some unifying property, attribute, or content. Thus, such terms as "coal-bearing zone," "marine zone," "calcareous zone," "tar zone," etc.

ZONE PLATE. A curious piece of diffraction apparatus, useful in illustrating certain aspects of the Huygens' principle. It consists of a transparent plate on which is a pattern composed of a very large number of concentric, opaque, circular rings with open spaces between them. They might be made by drawing on glass a system of circles whose radii are proportional to the square roots of the consecutive integers, and then covering every other annular space between these circles with black paint. Actually the rings must be so finely spaced that the design is first drawn to a large scale on white paper and a much reduced photograph of it then made on a glass slide. There should be two or three hundred of the rings. When finished, they look much like a set of Newton's rings.

A plate thus prepared, when placed across a beam of light, acts like a converging lens with its optical center at the center of the ring system. It will produce a faint, inverted, real image of a bright object, such as a candle. If there are N opaque rings and the radius of the outermost is R, then the focal length (see also **Mirrors and Lenses**) for light of wave-length l is $l = R^2/N\lambda$.

ZONE REFINING. One of a class of techniques known as fractional solidification, in which a separation is brought about by crystallization of a melt without solvent being added. See also **Crystallization**. Solid–liquid phase equilibria are utilized, but the phenomena are much more complex than in separation processes utilizing vapor–liquid equilibria. In most of the fractional-solidification techniques described in the article on crystallization, small separate crystals are formed rapidly in a relatively isothermal melt. In zone refining, on the other hand, a massive solid is formed slowly and a sizable temperature gradient is imposed at the solid–liquid interface.

Zone refining was developed in the early 1950s at Bell Telephone Laboratories in response to the need for extremely pure germanium [CAS: 7440-56-4]. It was an essential step for the development of the transistor and thus for the entire electronics revolution. Before that time, purification was carried out by normal freezing, also called progressive freezing. A melt was slowly frozen, causing more impurities to be concentrated in the last melt to freeze. In progressive freezing, however, a single solidification did not give sufficient purification. Simply remelting the entire ingot would redistribute the impurities, thereby eliminating the purification of the first solidification. the impure end could be removed, but handling and cutting introduce new impurities. The problem was solved by melting only a small part of the material and passing this molten zone down the ingot. Subsequent zone passes increased purification without requiring handling or cutting or permitting excessive back-mixing.

Zone refining can be applied to the purification of almost every type of substance that can be melted and solidified, eg, elements, organic compounds, and inorganic compounds. Because the solid — liquid phase

equilibria are not favorable for all impurities, zone refining often is combined with other techniques to achieve ultrahigh purity.

Because of the high costs of zone refining its application thus far have been limited to laboratory reagents and valuable chemicals such as electronic materials. The cost arises primarily from the low processing rates, handling, and high energy consumption owing to the large temperature gradients needed.

Actually, zone refining is only one of a class of techniques known as zone melting in which a molten zone is passed down a solid rod. Zone melting is used routinely to collect impurities in high purity materials, eg, silicon [CAS: 7440-21-3], in preparation for chemical analysis. Growth of bulk single crystals is an important application that includes commercial float-zoning of silicon crystals for the semiconductor industry. Floating-zone melting is being considered for use aboard the U.S. Space Shuttle because the absence of gravity might permit larger crystals to be grown with greater homogeneity.

Addition of solvent to the zone allows crystals to be grown that either decompose before melting (incongruent melting) or have a very high vapor pressure at the melting point. This technique has been called both temperature-gradient zone melting and the traveling-heater method of crystal growth. It has also been used for fabrication of semiconductor devices.

Continuous zone-refining techniques have been developed, both theoretically and experimentally.

Equipment and Techniques

Containers. The ideal container for zone melting should not contaminate the melt nor be damaged by the melt or subsequent contraction of the solid. For organic materials, borosilicate glasses are especially suitable, although metals and fluorocarbon and other polymers have also been successfully employed.

For many metals and semiconductors, fused silica (often erroneously called quartz) is ideal. Sometimes, the substance sticks to the glass and causes a break. Such breakage is prevented by coating the inside of the vessel with a film of carbon, conveniently deposited by passing acetone vapor through the glass tube at ca 700 °C (1292 °F). However, at high temperatures such coating may result in contamination with carbon [CAS: 7440-44-0] or silicon. Metals such as aluminum [CAS: 7429-90-5], with a high free energy of oxidation, react with silica glasses. In such cases, an oxide container of still higher free energy of formation is used, such as alumina [CAS: 1344-28-1] or even sapphire. Zirconia and boron nitride [CAS: 10043-11-5] have also been employed.

High melting inorganic salts and oxides are conveniently, albeit expensively, treated in noble-metal containers, platinum [CAS: 7440-06-4], rhodium [CAS: 7440-16-6], and iridium [CAS: 7439-88-5]. Refractory containers, such as graphite [CAS: 7782-42-5], molybdenum [CAS: 7439-98-7], and tungsten [CAS: 7440-33-7] in inert atmospheres, are also successfully employed for such salts. Low melting salts are refined in fused silica. Glassy carbon and pyrolytic graphite are good substitutes for ordinary graphite when carbon particles are a problem.

It is prudent to perform zone melting in a dry inert atmosphere. Oxygen causes most organic melts to oxidize slowly. Oxygen and moisture not only oxidize metals and semiconductors, but often enhance sticking to the container. Molten salts attack silica more rapidly in the presence of moisture. Oxygen and water are considered impurities in some inorganic compounds.

Moisture is removed from fused silica by heating, preferably in vacuum.

The container may either be in the form of a tube or a horizontal boat. A boat is advantageous for removal of the substance after zone melting, but may not be feasible if the substance is volatile.

Because the solid and melt differ in density, repeated zone passes can transport material along the container. If the substance expands upon melting, it tends to travel toward the front, and vice versa. With a horizontal boat, this can be avoided by tilting. The tilt can be adjusted in such a way that whenever a zone reaches the end of the ingot some melt overflows, thereby removing some impurity and preventing back mixing upon subsequent zone passes. Precautions must be taken with a sealed tube to prevent rupture of the container caused by material transport. With organic compounds that expand upon melting, provisions must be made for this expansion when the zone forms at the front end of the ampul by leaving an empty space at the front end, separated from the substance by a fluorocarbon polymer plug. Each time a new zone is formed, the plug is forced to move to take up the expansion.

Drive Mechanisms. Either the heaters or the sample may be moved. The optimal zone travel rates are typically rather slow, ie, ca 1 cm/h (0.39 in/h). Thus, electric-motor drives require gearing systems, resulting in an undesirably jerky stick-slip movement. This is avoided with double-rod supports with linear ball bearings and with low backlash gears, where tension on the moving piece pushes in the direction of motion.

Pneumatic and hydraulic drive systems have also been used, although not widely.

Heating and Cooling. Heat must be applied to form the molten zones, and this heat much be removed from the adjacent solid material. In principle, any heat source can be used, including direct flames. However, the most common method is to place electrical resistance heaters around the container.

Heat is often removed by simply allowing it to escape by convection, radiation, and conduction. However, such uncontrolled escape can lead to very large temperature fluctuations. It is better to surround the entire container, heaters and all, with a controlled-temperature cooled chamber. Even then, buoyancy-driven free convection from the ampul can lead to small temperature fluctuations. Jets of air or cooling water applied directly onto the ampul adjacent to the heater have been employed. Both temperature and flow rate of the coolant should be controlled.

Floating-Zone Melting. No completely satisfactory container material exists for many high melting materials. In such cases, floating-zone melting may be employed. Heat is applied to a vertical rod, usually by induction, electron-beam, or radiant methods. In early applications, the roughly cylindrical molten zone was held by surface tension, and rods of only a few mm in diameter could be zoned thereby. The demand for large-diameter silicon for semiconductor devices led to a modification. Typically, an induction-heating pancake coil is used with a diameter smaller than that of crystal. The melt collects in a puddle and freezes onto the growing crystal below. The electromagnetic field of the induction heating coil supports the molten zone. In this way, dislocation-free single silicon crystals of >10 cm dia (3.94 in dia) and almost 1 m (3.3 ft) long are grown commercially.

The primary application for floating-zone melting is crystal growth rather than purification. Semiconductor-grade silicon is not purified by zone refining; silicon chlorides are distilled and then reduced with hydrogen.

Additional Reading

Herington, E.F.G.: *Zone Melting of Organic Compounds*, John Wiley & Sons, Inc., New York, NY, 1966.

Pfann, W.G.: *Zone Melting*, 2nd Edition, John Wiley & Sons, Inc., New York, NY, 1966.

ZONE TIME. The idea incorporated in zone time was suggested by Sandford Fleming in 1878 for use in establishing standard time. Zone time is used at present by all branches of air and sea navigation of the United States, and many other nations. The surface of the earth is divided into 24 time zones, each covering 15° of longitude and each centered on a meridian some integral multiple of 15° (1 hour) from Greenwich, England. Each zone is given a number, known as the zone designation, which is the number of hours that the central meridian of the zone is west or east of Greenwich. The zone designations are marked plus (+) for west longitude and minus (−) for east. The zero zone, centered on the meridian of Greenwich, is split; the −0 zone extending from longitude 7°.5 East to 0; and the +0 zone extending from 0° to 7°.5 West. The same is true for the zone centered on 180°, where we have +12 extending from 172°.5 West to 180°; and −12 from 180° to 172°.5 East.

Times on the ship or plane are always expressed on a 24-hour system, with midnight as 00 hours, noon as 12 hours, and midnight as 24 hours the same date, or 00 hours the following date. For example, a ship in longitude 78°52′ East would express an afternoon time of $03^h\ 43^m\ 52^s$ as $(-5)\ 15^h\ 43^m\ 52^s$ ZT. Such a system avoids the use of the A.M. and P.M. designations, which so frequently lead to serious confusion. The 24-hour system of naming time is in use by all branches of the armed forces of the United States, by many European countries, and by some business houses in America.

For ordinary working purposes, when time is not needed closer than the nearest minute, time is always expressed in four digits. For example,

a ship in longitude 92°W would express 1 minute after midnight as (+6) 0001 ZT; a ship in longitude 130°E would express 6:34 P.M. as (−9) 1834 ZT. Since the zone designation corresponds to the longitude of the central meridian of the zone from Greenwich, Greenwich time can immediately be determined from zone time by the algebraic addition of the zone designation; e.g., if the zone time is (+4) 0946, Greenwich time is 1346. In transforming from zone time to Greenwich civil time, the civil calendar date must be carefully considered. If the ship's time and date is January 24 (+12) 1846 ZT, the Greenwich civil date and time is January 24, 3046 GCT, which should be expressed as January 25, 0646 GCT. Next, consider another ship, which may be only a few miles to the westward at this same instant. Since the Greenwich time is the same, we have the zone time for this ship as January 25 (−12) 1846 ZT.

ZOOCHLORELLA. A green plant cell (alga) living in the tissues of various animals, including flatworms, coelenterates, sponges, and one-celled species. The association is a true symbiosis (animal association). Yellow or brown symbionts of the same habits are called zooxanthellae.

ZOOECIUM. The body wall of the individual is colonies of Bryozoa. The zooecium acts as a sheath into which the polypide, consisting of the alimentary tract with the tentacles, can be retracted when the animal is disturbed.

ZOOGEOGRAPHY (also called Chorology). The distribution of animal faunas on the surface of the earth. According to the prevailing characteristics of their faunas, several zoogeographical regions are recognized as principal divisions. These are the Palaearctic region, including all of Europe, Asia south to the Himalayas, and Africa above Lat. 20°N. Some biologists include Greenland and Labrador in the same region, but they are usually regarded as part of the Nearctic region with the rest of North America. Central and South America and the West Indies are in the Neotropical region. The Ethiopian region includes Africa and Madagascar. The Australian region includes Australia, Tasmania, New Zealand, and many of the Pacific islands to the north and east. The Oriental region includes all of Asia south of the Palaearctic, with the large adjoining East Indian islands and some of the smaller Pacific islands to the east. Various subdivisions have been recognized by some writers.

Later studies of animal distribution have attempted to correlate it with climatic conditions. Merriam's classification of the North American fauna included three principal regions, boreal, austral, and tropical. In the first the Arctic zone is limited to high altitudes and latitudes where the mean normal temperature of the six hottest weeks is 50°F at the lowest boundary. The Hudsonian zone ranges from this limit to a mean of 57°F, and the Canadian zone from this to 64°F. The transition zone of the Austral has an upper limit, expressed as the sum of mean daily temperatures above 43°F, of 10,000. The Upper Austral extends from this limit to 11,500, and the Lower Austral to 18,000. Tropical regions have a total of 26,000; in North America they occur only in southern Florida.

Still other attempts to classify the distribution of organisms in North America in relation to climatic conditions have resulted in the isophanes and phenomeridians of Hopkins' maps and in biotic areas based on rainfall, temperatures, and floral characteristics. In modern ecology these studies have become intricately associated with more detailed analyses of the relations of organisms to the environment, but for the more general needs of taxonomists and specialists in other fields of biology the older terms of distribution are still useful.

ZOOLOGY. A branch of biology concerned with the animal kingdom and its members, both as individuals and as classes; as well as with aspects of animal life.

ZOOPLANKTON. See **Ocean**; and **Plankton**.

ZOOSPORANGIUM. A zoosporangium is a cell in which motile spores called zoospores are formed.

ZOOSPORE. A zoospore is a motile spore or reproductive cell that develops into a new plant. It is formed from the protoplast of the cell, usually by repeated divisions of the protoplast. Zoospores are asexual.

ZORAPTERA. An order of insects without a common name, made up of a few rare species found in the Oriental region, Africa, Central America, and the southern United States. They live in small colonies and resemble termites in appearance, although they differ conspicuously in the form of wings. As in the latter insects, some members of the colony are winged and some wingless.

ZORILLE. See **Cats**.

ZSIGMONDY REAGENT. A reagent for colloids which is a red colloidal solution of metallic gold obtained by reducing auric chloride by formaldehyde in the presence of an alkali. When mixed with sodium chloride, this reagent becomes blue because of an agglomeration of the particles of gold, but this color change is prevented by the presence of an adequate amount of certain other colloids. They can be classified according to the amount required to prevent the color change.

ZSIGMONDY, RICHARD (1865–1929). A native of Austria, Zsigmondy received the Nobel Prize in chemistry in 1925 for his demonstration of the heterogenous nature of colloid solutions and for the methods he used, which have since become fundamental in modern colloid chemistry. His most important contribution to chemistry was his invention of the ultramicroscope (with Siedentoph) in 1903.

See also **Tyndall Effect**; and **Ultramicroscope**.

ZWITTERION. An ion carrying charges of opposite sign, which thus constitutes an electrically neutral molecule with a dipole moment; looking like a positive ion at one end and a negative ion at the other. Most aliphatic amino acids form such dipolar ions, hence react with both strong acids and strong bases.

ZWORYKIN, VLADIMIR KOSMA (1889–1982). Zworykin was an American physicist and electronic engineer born in Mourom, Russia. He attended the Petrograd Institute of Technology receiving his degree in electrical engineering. With his professor, Boris Rosing, he worked on cathode ray tubes and thought about their use for displaying images. He came to the United States in 1919 and began working for Westinghouse Electric Corporation in 1920 on radio research. He became an American citizen in 1924 and received his Ph.D. in Physics from University of Pittsburgh in 1926. Zworykin is best known for inventing the iconoscope, or television pickup tube, and also for developing the kinescope, or television receiving tube. In 1929 he demonstrated an all-electric television system for the Institute of Radio Engineers at Rochester, New York. He was invited to join RCA to do commercial development of his invention. Zworykin's research came out of the lab and resulted in the invention of television.

Zworykin's contributions also include work on helping to develop the electron microscope. He was always particularly interested in the application of engineering and electronics in medicine and made important contributions.

Zworykin received many honors throughout his life some of which are, Rumford Medal of the American Academy of Arts and Sciences in 1941, the Medal of Honor of the Institute of Electrican and Electronic Engineers in 1951, and the Edison Medal of the American Institute of Electrical Engineers in 1953.

See also **Iconoscope**; and **Television (TV)**.

J. M. I.

ZYGOMATIC ARCH. A narrow bridge of bone extending, in the mammalian skull, from before the ear to the cheekbone, below the temple. It is composed of a long process of the temporal bone squamosal extending forward and joining a short posterior process of the malar jugal bone.

ZYGOSPORE. A spore formed by the union of two gametes of similar size (isogametes).

ZYGOTE. The cell that is formed from the union of two sex cells or gametes. In many of the algae the two fusing cells are identical in size. In many cases these two cells are actively motile, as is the zygote which they form by their union. In other cases the zygote is nonmotile from the

beginning. This is always true in the oögamous species of green algae and in all higher plants.

The zygote has at first a thin cell wall. Soon this thickens and becomes differentiated into layers. It then becomes a spore — a zygospore if formed from gametes of similar size, an oöspore if formed from gametes of unequal size (eggs and sperm).In the algae and fungi the zygote is often a stage in which the plant survives long periods of unfavorable conditions, such as drought or cold. In the higher plants the zygote fails to develop a thick wall and, by a series of cell divisions, becomes the sporophyte; in the seed plants, it becomes the embryo of the seed. See also **Cell (Biology)**.

ZYMOGENIC CELLS. Those cells of the stomach that secrete pepsin.

ZYMOLYTIC REACTION. A chemical reaction catalyzed by an enzyme, especially a reaction involving bond rupture or splitting, usually a hydrolysis.

Biological systems, acidosis in, 24
Biology
  comparative biology, 1251
  defined, 641
  ecology and ecological systems, 1695–1697
  evolution and, 1862–1864, 2255
  forensic chemistry and, 2062
  holotype, 2492
  homeotype specimens, 2493
  phenology, 4055
  radiobiology, 4419
  systematics and, 5324–5327

Bioluminescence, 641–642
  dinoflagellata, 1545
Biomass
  oceanic, 3774–3775
  waste as energy source and, 5781–5782
  water hyacinth, 5793–5795
Biomaterials
  biopolymers, 649–650
    bioresorbable polymers, 642–646
    xanthan gum, 5931–5932
  bone disorders and diseases, 755
  cardiovascular devices, 908–910
  metallobiomolecules, 3384
  microgravity, 3429–3430
  properties and applications, 642–645
  tissue engineering, 5463–5464
Biome. *See also* Ecology and ecosystems
  definition and characteristics, 646–648
  ecological research, 1695
  prairie, 4298
  rain forests, 4440–4441
  tundra, 5548
Biomechanics, bipedalism, 687–690
Biomedical devices
  biomaterials, 642–645
  fiber optics technology, 3811
  tantalum materials for, 5339
Biomimetic chemistry, 649
Bionics, 649
Biopak, 649
Biopharmaceuticals
  bioprocess engineering, industry growth and, 660–665
  regulatory issues, 662–665
Bioprocess engineering, 650–673
  biopharmaceuticals development, 660–665
  current trends in, 650, 655–656
  enzymes, 1823
  history, 650–656
  Human Genome Project and, 2561
  industrial biotechnology, 2674
  industrial enzymes, 665–667
  polymerase chain reaction and, 667–671
  regulatory issues, 662–665
  tissue engineering, 5463–5464
Biopsy, 675
  renal function, 2886
Bioremediation
  basic principles and applications, 675–679
  groundwater and soil, 677–678
  inorganic contaminants, 678–679
  organic contaminants, 675–677
  solvents, 4889
  water pollution, 5799–5800
Biosatellite, 679
Biosensors
  biopolymers, 650
  structure and applications, 679
Bioseparations, bioprocess engineering, 671–673
Biosolids
  treatment of, 680–682
  wastewater treatment systems, 5789–5790
Biosphere
  astrobiological research and, 405–415
  defined, 682
  polar regions, 4211
  prokaryotic cells and, 533
Biostratigraphy, 682
Biostrome, 682
Biosynthesis
  natural rubber, 4596–4597
  plant waxes, 4156–4158
Biotechnology
  bioprocess engineering, 650–673
  history, 682–685
  life cycle and value drivers in, 660–665
  microbiology and, 3416–3417
  microgravity, 2346–2347
  nanotechnology and, 3574
  pest control methods, 2726–2727
  pharmaceuticals, 4048
  prokaryotes in, 532–533
  trace and residue analysis, 5490
Biotic potential, 685
Biotin, structure and properties, 685–686
Biotite, 686
Bipedalism, zoological classification and characteristics, 686–690
Biphenyls, structure and properties, 690
Bipolar coordinates, 690–691
Bipolar pattern (lightning), 649
Bipolar technology, electronic memory, 3367
Bipolar transistors, analog signals and switches, 216–218
Biprism, 691
Bipyridinium herbicides, 2456
Biquadratic equation, 691
Bi-quartz, 691
Biquinary code, 1208
Biramous appendage, 691
Birch trees, botanical classification and characteristics, 691–692
Bird bursts, 692
Bird louse, 692
Bird of paradise, zoological classification, 692–693
Birds (Aves)
  anatomy and physiology, 693–694, 700
  anseriformes, 249–250
  apodiformes, 303–304
  apterygota, 307
  biodiversity of, 502–504
  bipedalism in, 687–690
  bird of paradise, 692–693
  bittern, 708
  blackbird, 709
  bluebird, 736
  bluethroat, 737
  bobolink, 738
  bowerbird, 778
  broadbills, 809
  bulbul, 826
  bullfinch, 827
  bunting, 828
  canary, 862
  caprimulgiformes, 880–881
  caracara, 882
  cardinal, 905–906
  cassowaries, 935
  charadriiformes, 1024
  chatterer, 1025
  chickadee, 1072
  ciconiformes, 1110–1111
  coliformes, 1220
  columbiformes, 1235–1236
  condor, 1281
  coots, 4435–4436
  coraciiformes, 1326, 2896–2897
  cowbird, 1363
  cranes, 2361, 4435–4436
  creepers, 1365
  crow, 1375
  cuckoos and coucals, 1392
  cuculiformes, 1392
  curassow, 1394
  dinosaurs, 1545–1549
  eagle, 1627–1628
  economic importance, 702
  emu, 1802
  endangered species of, 701–702
  falconiformes (raptors), 1883–1884
  falcons, 1883
  family names of, 696–700
  feathers, filoplumes and down, 700
  finch, 1935
  flamingos, 1965
  flowers for, 4023
  fossil history, 501, 2074–2075
  fringillidae, 2105
  galliformes, 2172–2173
  gaviiformes, 2197
  global warming and, 2299
  gnatcatcher, 2304
  golden-eye, 2310
  grackle, 2320
  grebe, 2353
  grouse, 2360
  gruiformes, 2361
  habitats and abundance, 504
  habits and lifestyles, 505–506
  hawks, 2392–2393
  herons, 1110, 2461–2462
  hoatzins, 2485
  hummingbirds, 5313
  ibis, 1110–1111, 2633
  internal rhythms and external signals of, 700–701
  jacana, 2839
  jay, 2847
  junco, 2856
  jungle fowl, 2856
  kiwi bird, 2898
  lark, 2934
  loons, 2197, 3111
  lyre bird, 3170
  magpie, 3209
  maleo bird, 3219
  manakin bird, 3226
  martin, 3332
  meadowlark, 3355
  megapode, 3360
  migratory habits, 694, 697, 700
  mound birds, 3541–3542
  mousebirds, 1220
  myna, 3567
  nightingale, 3638
  night jars/nighthawks, 3638
  nuthatch, 3725
  ornithology, 3857
  ostrich, 3867–3868
  ouzel, 3868
  owls, 3870, 5222–5223
  paleognathae, 3906–3909
  parrots and cockatoos, 3949–3950
  partridge, 3962
  passeriformes, 3963–3965
  peafowl (peacocks), 3983–3984
  pelecaniformes, 3988–3989
  penguins, 3991–3992
  petrels and albatrosses, 4023–4024
  pheasant, 4053
  phoenicopteri (birds), 4057
  phylogenetic classification, 501–502, 504–505
  piciformes, 4105
  pigeons and doves, 4106–4107
  podicipediformes, 4182
  procellariiformes, 4316

Birds (Aves) (*continued*)
psittaciformes, 4347–4349
ptarmigan, 4351
quail, 4370–4371
quetzal, 4385–4386
rails, 4435–4436
ratites, 4458
raven, 4458
redstart, 4468
repellents against, 4496
reproductive function, 506
rhea, 4512–4513
robins, 4534
screamer bird, 4686
shrike, 4769
sparrow, 5088
sphenisciformes, 5100
starling, 5183–5184
storks, 5217–5218
survival patterns, 505–506
swallow, 5298
swifts, 5313
tanager, 5337
thrasher, 5435
thrush, 5438
tinamiformes, 5460
tinamous (flightless birds), 5460–5461
tits, 5474
toucans, 5924–5925
tragopans, 5493
trogon, 5533
trogoniformes, 5533–5534
turacos, 1392, 5557
turkeys, 5560
vocalism of, 701
vultures, 5764–5765
waders, shorebirds and gulls, 5767–5768
warbler, 5771
waterfowl, 5791–5792
water metabolism in, 5785
waxwing, 5815
weaverbird, 5843
West Nile viruses (WNV) and, 5856
woodpeckers, 5924–5925
wren, 5928
zoological classification and characteristics, 501–506, 693
Birefringent filters, solar telescopes, 5279
Birkeland currents, 703
Birth control, vaccine approaches to, 5628
Birth process, statistical analysis, 704
Biserial correlation, 704
Bishop, J. Michael, 704–705
Bishop rings, 464
Bismaleimide polymers, 705
Bismuth, structure and properties, 705–706
Bismuthinite, 706
Bison. *See also* Buffalo
zoological classification, 706–707, 771
Bisphenol A resins, 1834–1835
polycarbonates, 4236–4238
Bisphenol F resins, 1835
Bit (data systems), 707
Bite injuries
centipedes, 1469–1470
chiggers, 1468
fleas, 1984
ticks, 1468
Bit plane approach, computer graphics, 1275
Bit string, manufacturing message specification, 3238
Bitterling, zoological classification, 707–708
Bittern, zoological classification, 708
Bitter patterns, 708
Bitumen, 708
maltha, 3224
tar sands, 5344–5347
Bituminous coal. *See also* Semibituminous coal; Sub-bituminous coal
basic properties, 1176
commercial sizes, 1177–1178
Bivalves, zoological classification, 708, 3498
Bivane, 708
Bixin, structure and properties, 244
Bjerknes, Vilhelm Frimann Koren, 708–709
Black, James Whyte, 711
Black, Joseph, 711
Blackbird, zoological classification, 709
Black body radiation
absorption (energy), 11
basic properties, 709
color and, 1231–1232
heat transfer, 2418
infrared radiation sources, 2711–2712
Black box unit, 709. *See also* Transponders
telephones, early history, 5356
Black Brant rockets, 4898–4900
Blackbrush acacia, 14
Blackfish, 709
Black-fly, 709–710
Black fog, 2024
Black frost, 710
Black holes
basic properties, 710
Beyond Einstein program, 616–619
Compton Gamma-Ray Observatory (CGRO), 1263
galaxies and, 2154, 2157
gravitational collapse, 2343
Hubble Space Telescope images of, 2524
star formation and evolution, 5153
x-ray astronomy, 5942–5944
Blackhorse (fish), 710
Black ice, 711
Black light, ultraviolet radiation, 5578
Blackout, 712
Black smoker, 712
deep-sea hot springs and cold sweeps, 3748–3751
hydrothermal vents, 2615
ocean minerals in, 3779
Bladder, urinary, structure and function, 2884–2886
Bladdernut trees and shrubs, 713
Bladder worm, 713
Blade element theory, propeller design, 110
Blagden law, 713
freezing point depression, 1381, 2098
Blast furnaces, iron production, 2813
Blastocoele, 713
Blastomere, 713
Blastomycosis
bacterial origins, 519
epidemiology and pathology, 713
Blastula, 713
Bleaches and bleaching agents
composition and applications, 713–716
detergents, 1479
hypochlorites, 2628
optical brighteners, 3803
peroxides, 715, 4007–4011
pulp production and processing, 4354–4356
Blended fabrics, dyes for, 1622
Blending height, 716
Blending systems
automatic devices, 3462
whiskies, 5874–5875
Blennies, zoological classification, 716–717
Blepharitis, epidemiology and pathology, 717, 1879
Blepharoplasty, 717–718
Blepharospasm, pathology, 718
Blind-fish, 718
Blindness
Braille system, 781
definitions of, 5712
Blind snakes, classification, 4825–4827
Blind worm, 718
Blister beetle, 718
Blizzard, 718–719
Blob (radar), 719
Bloch function/Bloch wall, 719
Bloch theorem, solid-state physics and, 4882
Blocking, meteorological, 719
Blocking capacitor, 719
Block switching, analog switches, 217
Blondel's theorem, electric power measurement, 1727–1728
Blood-brain barrier
basic principles of, 726–727
behavioral reactions to food, 1513–1514
catecholamine effects, 71–72
Blood (human). *See also* Plasma (blood); Platelets (blood)
access devices, 910
acidosis in, 24
agglutinin, 98
anemia and loss of, 229–230
anoxemia, 249
anticoagulants, 275–276
benzidine reaction, 603
chemistry, 633
clotting mechanisms, 720, 722, 727–730, 1158
brain injury and, 783–784
deep vein thrombosis, 1443–1444
hemophilia and, 730, 2438–2440
platelet activation, 4169
pulmonary embolism, 1443–1444
thrombosis, 5436–5437
coagulation, 730–735
cascade, 732–733
feedback controls, 733–735
thrombosis, 5436–5437
composition and properties, 719–725
disease markers, 725
eosinophils, 1827
erythrocytes, 720
frozen red cells, 724
glucose, sugar alcohols, 5254
granulocytes, 721–722
hemoglobin, 2437
hypocapnia, 2628
hypoxaemia, 2630
lymphatic system and, 3160–3162
lymphocytes, 721
megaloblasts, 720–721
molecular defects, 722
monocytes, 721
occult blood, 725
osmotic pressure, 722–723
oxygenators, 910
plasma, 720–723
platelets, 721–722
processing and transfusion therapy, 723–725
protein structure, 4335–4337
recycling of, 725
salvage techniques, 910
substitutes, 724–725
tests
angina, 238

coronary thrombosis, 1342
thrombin, 5436
von Willebrand factor, 722
white cells, 721
Blood (nonhuman)
in fishes, 1954
hemocyanin, 2436
hemolymph (invertebrates), 2437
homoiothermy, 2494
Blood pressure, 735
diet and, 1511–1512
hypertension and, 2626–2627
sphygmomanometer measurement, 5103
stroke pathology, 5225
Bloodstone, 735
Blood urea nitrogen (BUN), chronic fatigue syndrome diagnosis, 1106–1107
Blood worm, zoological classification, 735
Bloom (surface coatings), 735
Blower(s)
basic principles of, 736
coal burning systems, 834–835
Blow-fly, 736
Blowhole (rock), 736
Blowing dust/sand, 736
Blowing processes, glass manufacturing, 2274–2275
Blow-mold-fill-seal systems, food packaging technology, 2046–2048
Blow molding, food packaging containers, 2048
Bluebird, zoological classification, 736
Bluebottle, zoological classification, 736
Blue butterflies, zoological classification, 736, 839
Blue crab, 1377
Bluefin tuna, 5547
Bluegill, zoological classification, 736
Blue glow, optical properties, 736
Blue jets (meteorological), 736
Blue moon, 736–737
Bluethroat, zoological classification, 737
Bluetooth protocols, mobile devices, 3469
Bluff body, 737
Blumberg, Baruch Samuel, 737–738
Blumenbach, Johann Friedrich, 738
Blushing, lacquers and varnishes, 738
BMP (Windows bitmap), 1028
Boars. *See* Swine
Boas (snakes), 4828
Bobolink, zoological classification, 738
Bode plot, frequency response, 2101–2102
Bode's relation, 738–739
Bodying agents, food processing, 739–740
Body mass distribution, macroecology, 3181
Body weight, basal metabolism and, 565–566
Boerhaave, Herman, 740
Bog/bog lakes, 740
muskeg, 3555
swamps, 5298–5299
Boguer's law, extinction coefficient, 1869
Bohr, Niels Henrik David, 740
Bohrium (element 107)
classification and characteristics, 107
nomenclature and history, 1053
Bohr liquid drop model, binding energy, 625
Bohr magneton, 740
Boids, artificial life and, 355
Boids/boidea (snakes), 4827–4828
Boiler systems
bent-tube boilers, 744–745
boiling-water nuclear reactors, 3693–3696
combustion principles, 745–746, 1237–1243
convection principles, 746
design criteria, 745–748
feedwater, 1891–1894
fossil fuel power plants, 747–748
integral-furnace boiler, design and properties, 744
ribbed tubes, 742
steam separation and purity, 742–744
steam-temperature adjustment and control, 747
structure and classification, 741–748
superheaters and reheaters, 746–747
Boiling
basic principles, 749
curve and condensation curve, 749
ebulliometer/ebullioscope measurement, 1687
ebullition, 1687
point and point constant, 749–750
point elevation, 750
Boiling-point diagrams, distillation, 1569
Boiling-point rise system, specific gravity measurements, 5091
Boiling-water reactor (BWR)
nuclear power technology, 3692–3696
uranium and, 5608
Boils
on ear, 2399
folliculitis and, 2027
pathology, 750, 1467
Boise de rose oil, 750
Bole (rock), 750
Bolide meteor fragments, 750
fireball, 1938
Boll weevil, 750
Bollworm, 751
Bolometer, 751, 2924–2925
Bolometric magnitude, defined, 9
Bolson, 751
Boltzmann, Ludwig, 751
Boltzmann constant
activation energy, 49
chemical reaction rate, 1066–1068
colloids, 1226
defined, 751
ideal gas law, 2639
Boltzmann's distribution law, 751–752
Boltzmann theorem
equilibrium, 1838–1839
kinetic theory, 2895–2896
Boltzmann transport equation, 752, 5515–5516
Bolus, 752
digestion and, 1524
Bombardier beetle, 752
Bombardment, atomic and nuclear, 752
Bond albedo, 752
Bond angle, covalent bonds, chemical elements, 1050
Bonded abrasives, properties, 7
Bonds, chemical
basic properties, 752
bond energies
chemical elements, 1051
inorganic polymers, 4251–4252
bond lengths, covalent radius, 1045–1048
bond order, covalent radius, 1045, 1047
chemical association and, 384–385
covalent radii, 1045–1050
formulas for, 1065
sonochemistry and, 4894
triple bonds, 1050–1051, 5533
Bone-derived growth factors (BDGF), bone calcification and, 754
Bone marrow transplantation (BMG), 758, 5512
Bone morphogenetic protein, bone calcification and, 754
Bone(s)
acoustic emissions, 755, 759
calcification, 754
calcium in, 851
cartilage and, 755
connective tissue, 1290
density, 756–757
disorders and diseases of, 755–758
radionuclide scanning, 4412
epiphysis and, 1833
foramen, 2059
formation biochemistry, 753–755
fractures, 755
hand anatomy, bones in, 2385–2387
hyperthyroidism and, 757
myeloma, 758
osteoarthritis, 3866
osteomalacia, 757
osteomyelitis, 756
osteopetrosis, 757
osteoporosis, 756
Paget's disease, 757
phosphates in, 4071
pressure measurements, 755–756
quadrate bone, 4369
reconstruction, 754–755
structure and composition, 752–758
temporal bone, 5394
traumatic disorders, 757–758
Bone staples and plates, shape-memory alloys for, 645
Bonner Durchmusterung star catalogue, 759, 5167
Bonnet, Charles, 759
Bony fishes, classification and taxonomy, 1949–1952
Bony-tail (fish), 759
Bony tongue (fish), 759
Boobies, 3988–3989
Book louse, 759
Boolean algebra, 137
basic principles, 760
binary state, 623
manufacturing message specification, 3238
Boole's inequality, 760
Boom (structural), 760
Booster
amplifier, 206
electrical, 760
Booster effect, vaccines, 5625–2626
Boosting process, machine learning, 368
Bootes (constellation), 760
Bootstrap processes and devices
amplifier, 206
defined, 760
Boracite, 760
Bora fog, 2024
Borane
composition and properties, 760
hydroboration, 2584
organoborane, 3845
Borates
calcium, 849
lead, 3000
magnesium, 3190
structure and properties, 764
Borax, composition and properties, 760
Bordet, Jules Jean Baptiste Vincent, 760–761
Bordoni peak, 761
Bore, tidal, 763
Borehole storage, barometric efficiency, 562
Borelli, Giovanni Alfonso, 761

Borer insects
cane-borer, 4457
European corn borer, 1856
flatheaded apple tree borer, 762
leadcable borer, 1593
lesser grain borer, 2323
peach tree/twig borers, 762, 3983
pear tree borer, 762
potato stalk borer, 762
zoological classification, 716–762
Boric acid
flame retardants, 1960
structure and properties, 764
Borides
magnesium, 3190
refractory materials, 4479
structure and properties, 764–765
titanium, 5469
Boring
of soil, 763
tunnel engineering, 5552–5555
Born, Max, 763
Born approximation, 763
Bornite, 763

Continuous casting, steelmaking, 2817–2818
Continuous cell lines, viral structure, 5700
Continuous channel capacity, information theory, 2692–2693
Continuous deformation, 1450
Continuous-fiber production, fiber glass, 1911–1913
Continuous-flow stirred-tank reactor (CSTR)
  design and components, 4460
  industrial applications, 4462
Continuous function, 1300–1301
Continuous information sources, information theory, 2690
Continuous pressure filters, 1934
Continuous processes, adsorption and liquid separation, 74
Continuous truss bridge structures, 803, 805
Continuous variable, 1301
Continuous-wave radar, 1301
Continuum dynamics, fluid and fluid flow, 2008
Continuum emissions, radio astronomy, 4418
CONTOUR (Comet Nucleus Tour) program, 1560
Contours, 1301
Contractile proteins
  actin, 44
  basic properties, 1301
  chemistry of, 4335
Contractile vacuole, 1301
Contractility
  actin, 44

basic properties, 1301
Contraction hypothesis, stellar classification and, 5154, 5161
Contrast, statistical, 1301
Contrast agents, magnetic resonance imaging, 3200–3201
Control action, 1301–1304
feedback, 1889
multiposition controller, 3548
statistical quality control, 4373–4374
Control chart, statistical quality control, 1303–1304
Control element assemblies, pressurized-water nuclear reactors, 3699–3700
Control instructions, digital computer systems, 1531–1532
Controllable-pitch propeller, design fundamentals, 110–111
Controlled environment, 1822
food preservation and, 2050
hypobaric systems, 2627–2628
Controllers
adaptive control, 52–53
basic principles of, 1304–1305
floating, 1304–1305, 1988–1989
fluidics of, 2011–2012
hydraulic controller, 2579–2581
multiposition controller, 3548
pneumatic controller, 4178–4179
programmable controller
communications, 4321–4323
components, 4319–4320
defined, 4317
functions, 4318–4319
historical background, 4317–4318
input/output systems, 4320–4321
reverse acting, 4510
sampling controller, 1305, 4613
self-operated, 4711
servomechanism/servomotor, 4734–4735
Controlling genes, structure and function, 2209
Control logic, digital-to-analog (D/A) converter/conversion, 1542–1543
Control rods, boiling-water nuclear reactors, 3693–3697
Control systems
actuator, 51
adaptive control, 52–54
air pollution management, 4231–4232
architecture, 1309–1315
cathode ray tube operator stations, 1311–1313
data highways, 1310
direct process control, 1309
microprocessor-based controller, 1310–1311
process monitoring and managment, 1309–1310
artificial intelligence, 1315
basic components, 1306–1309
computer animation, 1272–1273
cybernetics, 1403
governor devices, 2320
hierarchy, 1309
higher-level supervisory control, 1313–1314
personal computers, 1315
photoelectric detectors, 4343–4344
plantwide control design, 1315
primary element, 4310
rectifiers, 4466

Deep Space 1 mission
  autonomous navigation, 3630
  Beacon Monitor Technology, 3630
  Ion Engine program, 3630
  New Millenium Program, 3628–3631
  Small Deep Space Transponder (SDST), 3630–3631
  solar system research, 4996–4997
  Space Technology 8 mission and, 5082–5087
Deep Space 2 mission, solar system research, 4997
Deep Space Information Facility (DSIF), Apollo program, 4935–4937
Deep Space Network (DSN)
  antennas, 257, 1438–1443
  asteroid exploration, 395
  astronomical interferometry, 1441
  Cassini-Huygens mission, 934–935
  Galileo Jupiter mission and, 2164–2165
  overview, 1438
  Pathfinder Mission to Mars, 3972–3980
  Phoenix mission to Mars, 4060–4063
  radio link, 1438–1439
  scientific research, 1440–1441
  spacecraft telecommunications and, 4904–4905, 4909
  Spitzer Space Telescope, 5116
  teams, 1441
Deep surveys, Chandra X-ray Observatory, 1020–1021
Deep vein thrombosis
  anticoagulant therapy, 276
  classification, 5437
  epidemiology and pathology, 1443–1444
Deepwater petroleum production, 4034–4036
Deer, zoological classification, 1444–1446
Deer fly, 1444
  repellents against, 4495
Defense Advanced Research Projects Agency (DARPA), internet history and, 2756–2760
Defense Commercial Telecommunications Network (DCTN), 5369–5370
Defense Meteorological Satellite Program (DMSP), 5819
Defervescence, 1446
Deficiency disease, pathology, 1446
Deflagrating explosives, 1867–1868
Deflation, geologic, 1446
Deflection
  angle, 1447
  structural, 1447
  vertical, 1447
  yoke, 1447
Deflector, defined, 1447
Defluoridation, 1447–1449
Defoaming agents, 1449–1450
  silicas, 4776
Deforestation
  climatology and, 1142–1143
  defined, 1450
Deformable objects, computer animation, 1271–1273
Deformation
  bands, 1450
  elasticity, 1707–1709
  hot working deformation, 2516
  materials, 1450
  mathematical, 1450
  plastic deformation, 4167
Degasification, 1450
  water, 5786
Degeneracy
  Coulomb, 1359
  exchange degeneracy, 1864
  gas kinetics, 1450
Degenerate state, 1450
De Graaf, Regnier, 1450–1451
Degradation
  chemical, 1451
  energy, 1451
  leaching process, 2996–2997
  light-emitting diodes, 3030
  Miescher degradation, 3438
  nuclear, 1451
Degree days, 1451
  growing degree day, 2360
Degree of dissociation, 1567
Degrees of freedom, 1451, 2090–2091
  robotic axes of motion, 4537
Dehiscience
  botanical, 1451
  stamen structure and function, 5149–5050
Dehumidification, 1451–1452, 1455
  drying process and, 1604–1606
Dehydration
  chemical, 1452
  drying processes, 1605–1606
  flame resistance, 1964
  food preservation, 2052–2053
  freeze-drying, 2095
  kidney and urinary tract function and, 2886
  Mitsunobu reaction, 3460
  physiological, 1452–1453
  water deficiency, 5785–5786
Dehydrochlorination, reaction mechanisms, 3840
Dehydrocyclization, catalytic cracking, 94
Dehydroepiandrosterone (DHEA), deficiency, aging and, 2256
Dehydrogenases, coenzymes, 1212
Dehydrogenation
  basic principles, 1453
  catalysts, 941
  reaction mechanisms, 3841
  styrene manufacture, 5232
Deimos (asteroid), 392
Deimos (Mars satellite), 3275, 3277
Deionization potential, 1453
  water treatment, 5788
Deisenhover, Johann, 1453
De Jussieu, Antoine-Laurent, 1453
Delay
  absolute, 9
  circuit, 1453
  defined, 1453
Delay equalizer, 1453
Delay line, 1453–1454
  microwave acoustics, 36–37
Delbrück, Max Ludwig Henning, 1454–1455
Delbrück scattering, 4668
Deliquescence, 1451–1452, 1455
Del operator, 1453
Delta connection, 1455
Delta function, 1455
Deltas, 1455
  hydrology, 2603
Delta Space Launcher program, 2985–2986, 2989–2990
Delta waves (sleep), 4813–4814
Delta Works (Netherlands), 1993
Demagnetizing field, 1455
Demal solution, 1455
Dementias
  epidemiology and pathology, 173–175
  geriatrics research, 2251–2252
Demerara sugar, 5249
Demineralization, 1455
  feedwater softening process, 1893–1894
  water treatment, 5788
Demodulator, 1455–1456
Demospongiae, 1456
Dempster-Shafer rule, 1006
Demyelinating diseases, multiple sclerosis, 3547

Denaturatization, catalysis, 939
Dendrites
  crystals, 1456
  neurons, 985–986
Dendritic growth models, space-based experiments, 4971
Dendrochronology
  basic principles, 1456–1457
  radioactive dating and, 4416
Dengue fever/dengue hemorrhagic fever
  epidemiology and pathology, 1457–1459, 2442
  flaviviruses and, 1973
Denitrification, 1459
Denoxification, stratospheric ozone, 5221
Dense-media separation, 1126
  coal preparation plants, 1182–1184
Dense properties, 1459
Densitometry, bone, 756–757
Density
  air, atmospheric pressure, 468–469
  ballistic, 549
  basic principles, 1460
  bone, 756–757
  cabbeling, 841
  critical density, 1370
  current, 1396
  electric flux, 1725
  ion, 2789
  ion-exchange resins, 2791–2792
  maple syrup production, 3250
  potassium, 4275
  power density spectrum, 4291
  river basin drainage, 4533
  seawater, 3741–3742
  sensors, ultrasonics, 5572
  of states, amorphous semiconductors, 4712–4714
  of steam, 5187–5188
  thermal insulation, 2733
  thin film technologies, 5427
Dentifrices, 1460–1462
Dentistry. *See also* Teeth
  caries and cariology, 911
  dental rinses, 1462
  dentifrices, 1460–1462
  dentition, 1463
  periodontitis, 4002–4003
  shape-memory alloys for, 645
Deodorants, vegetable oils, 5653
Deoxidizing agents, 1463
Deoxyribonucleic acid (DNA). *See also* Nucleic acids; Ribonucleic acid
  adenine, 56
  alkylating/cross-linking chemotherapeutics, 1070
  amplification, Human Genome Project and, 2553–2554
  basic properties, 1463
  binding/cleaving chemotherapeutics, 1070–1071
  bioprocess engineering and, 671–673
  cell division and, 966–969
  chromatin, 1096
  coding sequences, oncogenes and, 3794–3796
  enzyme feedback control, 1826
  forensics, Human Genome Project and, 2560–2561
  papillomaviruses, 3928–3929
  prokaryotic bacterial structure, 530–532
  radioprotective agents and, 4428–4432
  recombinant DNA, 4465
  replication, 2213
  sequencing technologies, radioactive elements, 4404
  structure and characteristics, 2209–2210, 3716–3717
  viruses, 3792–3794, 3796–3799
Departure from nucleate boiling (DNB) principle, boiler systems, 741–742
Departure (navigational), 1464
Dependency, alcoholism, 126
Dependendable Multiprocessor, Space Technology 8 mission research, 5082–5084
Dephlegmation, 1464
  distillation, 1569
Depleted uranium, 5608
Depletion theory of acquired immunity, 2660–2661
Depolarization, definitions, 1464
Deposition process, 1464
  plasmas, 4160
  vacuum deposition, 5638
Depressants, mixing operations, 1126
Depressed pole, 1464
Depression
  atmospheric pressure-gradient, 454
  manic-depressive illness, 3231–3232
  mood disorders, 3517–3520
  positron emission tomography, 5951
Depth of field, 1464–1465
Depth preferences, of fishes, 1955–1956
Derecho winds, 1465
Derivative action gain, 2152
Derivatives
  acrylic acid, 42
  carbon, 2722
  chemical, 1466
  coal tar, 1195–1197, 5342–5343
  control action, 1301–1303
  hydroxylamine, 4464
  indole, 2671
  mathematical, 1466
  methacrylic acid, 1402
  monoallyl, 154–156
  oxalic acid, 3871–3872
  peptone, 3995
  phosphonic acid, 2724
  pregnane, 2302
  thiophene, 5432
  toluene, 5476–5479
  urea, 5616–5618
  vector, 5651
  vitamin A, 5726–5729
Derjaguin-Landau-Verwey-Overbeek (DLVO) theory
  colloids, 1226
  zeta potential, 5971–5972
Dermal layers (plants), 4136–4137
Dermaptera, 1466
Dermatitis/dermatosis
  mechanical irritants, 1466
  pathology, 1466–1472
  pityriasis, 4125–4126
  ulcers, 5567–5568
Dermatomyositis, classification, 3567–3568
Dermatophytosis, pathology, 1472–1473
Dermestid beetles, 1473
Dermolith, 1473
Dermoptera, zoological classification, 1473
Desalination process, 1473–1476
  raw water treatment, 5786–5787
  saline gradients, ocean energy conversion, 3773–3775
  semipermeable membrane, 4726
  water resources, 5806–5807
Desargues, Girard, 1476
Descartes, Rene, 1476–1477
  folium of, 2026
Descending node, planets and comets, 1477
Descent Imager and Spectral Radiometer (DISR), Cassini-Huygens mission, 930–931
Describing function, 1477
Descriptive geometry, 1477
Desertification, 1477
  playa basins, 4173
Deserts
  biomes, 646–647
  global warming and, 2298
Design process
  computer-aided design, 490
  experimental design, 1477
Desorption, 1477
  freeze-drying, 2094
Detachable link chain, 1010–1011
Detection techniques
  electrophoresis, 1783
  radio, 1477–1478
Detectors and detector technology. *See also* Sensors
  balanced detector, 546–547

supercharger, 5279–5280
Internal conversion, 2749
Internal energy, 2749
thermodynamics and, 5414
Internal firewalls, 1941
Internal gravity wave, 2749
Internal pressure, defined, 4308
Internal water circulation, 2749
International candle unit, light measurement, 872–873
International Date Line, 2479, 5450
International Decade of Ocean Exploration (IDOE), 2639–2670
Coastal Upwelling Systems Analysis program, 3777–3778
deep-sea hot springs and cold seeps, 3748–3751
ocean current research, 3756
sea level research, 3740–3741
International Earth Rotation Service (IERS), astrometric research, 420
International Earth-Sun Explorer-3/International Cometary Explorer mission, 4997
International Extreme Ultraviolet Hitchhiker, universe research, 5021
International Gamma-Ray Astrophysic Laboratory (INTEGRAL), universe research by, 5013–5014
International Pyrheliometric Scale (IPS), 10
International Reference Stars (IRS), 5168
International Space Station
Columbus Laboratory, 5073
Destiny Laboratory Module, 5068–5069
Express Pallet, 5072–5073
goals and achievements of, 5056, 5059–5075
integrated truss structures, 5067
Japanese Experiment Module, 5071–5072
John F. Kennedy Space Center support for, 4965–4966
Joint Airlock, 5070–5071
microgravity research, 2348
mission schedule for, 5060–5061
Multipurpose Logistics Modules, 5069
photovoltaic module, 5067–5068
radiator system, 5068
research activities, 5073–5074
Space Station Remote Manipulator System, 5069–5070
Unity Connecting Module, 5063–5064
X-38 Crew Return Vehicles, 5073
Zarya Control Module, 5060, 5063
Zvezda Service Module, 5064–5067
International System of Units, 5587–5596
International Telecommunications Satellite Organization, 5318
International Telecommunications Union (ITU), 5358–5359
International telephony systems, current statistics for, 5358–5359
International Ultraviolet Explorer
ultraviolet astronomy, 5576
universe research, 5023–5024
International Union of Biochemistry and Molecular Biology (IUBMB)
chemical nomenclature, 3672–3673
protease classification, 4329–4330
Internet
ARPANET concepts, 2758–2759
broad community formation, 2762
commercialization, 2762–2763
Core Four standards, 2752–2753
documentation role, 2760–2761
extranets and, 1875–1876
file types on, 1927–1929
firewalls, 1939–1944
forensic applications, 2755
origins of, 2756, 2758
password systems on, 3965–3970
security standards, 2749–2755
telephony and influence of, 5359
threats and defenses in, 2750–2755
timeline, 2757–2758
Transmission Control Protocol/Internet Protocol (TCP/IP)
address resolution, 5506
applications, 5507–5508
asynchronous transfer mode, 5502
basic principles of, 5501
earth-orbiting satellites, data receiving and handling facilities, 1659–1663
ethernet, 5502
handshake, 5505
ICMP protocol, 5506
internet protocols, 5502–5504
layers, 5501–5502
point-to-point protocol, 5502
ports and connections, 5504
protocol stack, 5502
reliable transmission, 5504
security, 5506–5507
serial line internet protocol, 5502
state diagram, 5505
storage area networks, 5215–5216
timers, 5505
UDP protocol, 5505–5506
vulnerabilities, 2752–2753
widespread infrastructure, 2760
wireless communications applications, 5907–5914
Wireless Web technology, 5912
Internet Control Message Protocol (ICMP), 2753
transmission control protocol/internet protocol (TCP/IP) and, 5506
Internet Engineering Task Force (IETF), internet security, 2750–2752
Internet protocol (IP), 2752–2753
transmission control protocol/internet protocol (TCP/IP), 5502–5503
wireless communications applications, 5906–5907
Interphase, cell division, 966–967
Interplanetary coronal mass ejections (ICMEs), solar wind properties, 4878
Interplanetary dust, 1877–1878, 5118
Interplanetary medium (IPM)
solar wind properties, 4878
structure and characteristics, 2764–2766
Interplanetary Monitoring Platform, solar explorations, 5008
Interpolation, mathematical, 2766
Newtonian formula, 3631–3632
Interpreter code, computer systems, 2766–2767, 4346
Interrogation, Recording, and Location System (IRLS), Nimbus Satellite Program, 3646
Interrupt, computer systems, 2767
Interstellar dust, Stardust mission research and collection of, 5174–5175, 5180–5182
dust flux monitor system, 5181–5182
Interstellar medium
bow shock, 778–779
cosmic water, 1352–1354
heliopause, 2430
Spitzer Space Telescope research, 5120–5122
Voyager space mission, 5764
xenon, 5935–5936
Interstellar plasma, anomalous cosmic rays, 247–248
Interstellar reddening, 2767
Interstice, particles, 2767
Interstitial compounds, 2767
vanadium, 5643–5644
Intertrigo lesions, pathology, 1466
Intertropical convergence zone (ITCZ), evaporation and, 1859–1860
Intestinal parasites
nematodes, 2767–2771
protozoa, 2771–2772
Intestines
digestion, 1524–1525
geriatrics research on, 2252
transplantation, 5513
Intoxication
food allergies, 1512
water, 5785
Intra-abdominal abscess, 7–8
Intraaortic balloon pump (IABP), 909
Intracapsular cataract extraction (ICCE), 2772
Intracellular signaling pathways, cytokines, 1418

fluorescent lamps, 2642–2644
high-intensity discharge, 2644–2645
as light sources, 2642–2645
metal halide lamps, 2644
Land-based gas turbines, 2190
Lander systems
on Mars Exploration Rovers (Spirit and Opportunity) mission, 3308–3309
for Mars missions, 3290–3291, 3295
Viking spacecraft, 5684–5687
Landing facilities, Space Shuttle, 5044
Landing gear, 2924
Landing skid, 2924
Landsat Program, 1649, 2924
Data Continuity Mission, 4991
earth exploration by, 4989
history of, 4631–4637
Landsat Data Continuity Mission (LCDM), 1654
Landsberger method, boiling point elevation, 750
Landvaults, water pollution and, 5800–5801
Langley, Samuel Pierpont, 2924–2925
Langley unit, 2924
solar energy availability and, 4862
Langmuir, Irving, 2925
Langmuir adsorption isotherm, 75
Langmuir-Blodgett films
applied research areas, 3484–3489
historical review, 3481–3484
Langmuir circulation, 2925
Langmuir layer, 2925
Langmuir number, 2925
Langmuir probe, 2925
Language-based application processor, control systems, 1313
Language(s), computer, 2925–2926
La Niña, 2926–2928. *See also* El Niño
Lankester, Edwin Ray, 2928
Lanosterol, 5209
Lantern fly, 2928
Lanthanides
contraction, 44–45, 2928
discovery of, 4449
series, 2928
Lanthanum
actinium and, 46–47
nomenclature and history, 1057
as rare earth element, 4450–4455
structure and properties, 2929
Laparoscopic cholecystectomy, 2171
Laplace equation, 2929, 2933
electromagnetic radiation, 1758–1760
tidal energy and, 5445
velocity potential, 5659–5660
Laplace theorem, 2929
Laplace transform, 1318
basic principles, 2929–2933
transfer function, 5494
Lapping surface preparation, 2933
Lapse rate (atmospheric), 451, 2933
Larch tree, 2933–2934
Large Angle and Spectrometric Coronagraph (LASCO), solar explorations, 5004
Large Binocular Telescope Interferometer (LBTI) Origins program, 3852
universe exploration by, 5015–5016
Large eddy model/large eddy simulation, 2934
Large Magellanic Cloud
configuration of, 2159–2161
Supernovae 1987A and 1993J and, 5285–5287
Large numbers, law of, 2994
Large-scale integration (LSI), integrated circuits, 2738–2739
Lark, 2934
Larmor radius, plasma physics, 4158–4159
Larmor's theorem, 2934–2935
Larva, 2935
Larynx
anatomy, 2935
diseases of, 2935
injury, 2935–2936
papillomas, 3929–3930
voice and sound production, 5742–5744
Laser beam fusion technology, fusion power research, 2148
Laser-Doppler instrumentation, nonintrusive measurements, 4461–4462
Laser Interferometer Space Antenna (LISA), 617–619
design and instrumentation, 2939–2941
gravitational wave research, 2938–2939
mission and goals of, 2936–2938
ST7 mission research, 5080–5082
universe exploration by, 5017
Laser photolysis
chemical reaction rate, 1066–1068
femtochemistry, 4075
photochemistry and, 4073–4075
Lasers (light amplification by stimulated emission of radiation)
applications, 2946–2951
atmospheric remote sensing, 2948–2949
categories, 2942–2946
compound semiconductors, 4717–4718
definition, 2941
doppler flowmeter, 2950
eye surgery and, 2952–2953
fiber optics technology, 3807–3809
geophysics research, 2949
glasses, 2272
gyroscope, 2950
historical perspective, 2941–2942
holography, 2490–2492
infrared radiation, 2711
isotope separation, 4161
liquid lasers, 2945
in manufacturing operations, 2950–2951
Mars exploration, laser-induced remote sensing, 3299
mass spectrometry and, 3337
metallic coatings, 3383
metrology, 2949–2950
microminiaturization, 2944–2945
principles of, 2942
rare gases, 4456
recording systems, 2951
solid-state technology, 2944
spectroscopy, 2947–2948
weather satellites, 5821
X-ray lasers, 2945–2946
Laser surgery
laser in-situ keratomileusis (LASIK), 2936, 2952, 4475
laser thermal keratoplasty (LTK), 2953, 4475
nephrolithiasis, 2888–2889
Lassa fever, 2953–2954
Latency, herpesviruses, 2463
Latent heat
basic principles, 2954
of vaporization, evaporation and, 1858–1860
Lateral fold lizards, 3097
Lateral force, 2954
Lateral line, in fish, 1954
Lateral mirage, 2954
Laterite decay (geological), 2954–2955
Latex. *See also* Rubber

Linke scale
defined, 3052
sky color, 463
Linnaeus, Carl, 3052–3053
systematics and, 5324–5327
taxonomy and, 5349–5351
Linoleate, ammonium compounds, 194
Linoleic acid, 3053
radioprotective agents, 4431
Linolenic acid, 3053
Linseed oil, 1603–1604
Lion, zoological classification and characteristics, 951–952
Liouville equation, 3053
Liouville-Neumann series, 3053
Lipidoses, pathology, 3054
Lipids
diabetes mellitus physiology and biochemistry, 1486
diet and disease and, 1508–1509
structure and function, 3054
Lipmann, Fritz, 3055
Lipoma, 3055
Lipoproteins, cholesterol, 1088–1089
Liposomes, 3055
vaccine development and, 5628
Lipscomb, William N., 3055–3056
Liquation, definitions, 3056
Liquefaction
coal conversion process, 1194–1195
in earthquakes, 1677
helium, 2432
Liquefied natural gas (LNG), characteristics and applications, 3585
Liquefied petroleum gas (LPG), miscible recovery, 4036
Liquid atomizers, spray processes, 5132
Liquid-ceramic process, 1002
Liquid chromatography (LC)
adsorption and liquid separation, 74
basic properties, 3056
biopolymers, 649–650
Liquid chromatography/mass spectrometry (LC/MS), trace and residue analysis, 5489
Liquid-column chromatography, basic principles, 1100
Liquid crystal display (LCD)
active matrix addressing, 3062–3067
addressing schemes, 3059
cadmium-selenide transistors, 3071
calculator development, 853–854
cholesteric, 3072–3073
color filters, 3075–3076
dynamic scattering mode, 3072
electronically controlled birefringence, 3072
ferroelectric LCD, 3071
flat panel display technology, 5390
grayscale imaging, 3067–3068
guest-host, 3072
liquid-crystal-on-silicon devices, 3073
materials, 3074–3075
mobile devices and protocols, 3465–3469
multiplexed TN-LCD operation, 3060–3061
operating principles, 3057–3059
passive matrix operation, 3061–3062
polarizers and film compensators, 3076
polycrystalline silicon materials, 3068–3071
polymer-dispersed liquid crystal display, 3071–3072
reflective and transflective devices, 3073–3074
on silicon, 3418–3419
single-crystal silicon transistors, 3070–3071
surface alignment, 3075
technology of, 3056–3076
telephony, customer premises equipment, 5360
thin-film transistors, 3064–3067
twisted-nematic operation, 3059–3060
vacuum fluorescent displays, 5639–5640
Liquid crystal materials
biological systems, 3079
cybotaxis, 1403
fluid orientation and position, 3076–3077
materials, 3076–3079
polymers, 3078–3079
polyesters, 4240–4241
polymethylbenzenes, 4254
polymorphism, 3078
thermotropic, 3077–3078
Liquid-expanded film, 1930
Liquid helium, 2432
Liquid-in-glass thermometer, 3079
Liquid junction, 3079
Liquid lasers, 2945
Liquid-liquid extraction, principles and processes, 1870–1873
Liquid-liquid phase separation, tissue engineering, 5464
Liquid petroleum gas (LPG)
diesel engine fumigation, 1506–1507
properties, 4326
Liquid-phase metallization, metallic coatings, 3382
Liquid-phase projectors, loudspeakers, 3113
Liquid-propellant rocket engine, 3079
Liquids
consolute, 1293
electrorheological fluids, 3082–3083

Liquids (*continued*)
evaporation, 1856–1860
flow properties, 1998–2007
freezing point, 2098
geothermal energy systems and, 2248
hydrometer measurements, 2608
interfacial tension, 2745
mixing of, 3083
multiphase flow, 3084
plait point, 4126
polymer liquids, 3083
pycnometer, 4360–4361
salt bridge, 4612
separation, adsorption, 74
sonochemistry, 4892–4894
state, definition of, 3079–3080
structure and properties, 3056, 3080–3082
sulfur as, 5259
surface chemistry, 5294
surface forces, 3082
thermal flashing, 1966
Liquid-solid extraction, 1873–1875
Liquid-solid interface, sonochemistry, 4893
Liquidus curve
alloy phase diagrams, 152–153
defined, 3084
Liquid-vapor systems, boiling point, 749–750
Lissajous, Jules Antoine, 3084
Lissajous technique
cathode-ray tubes, 948
frequency measurement, 2099–2100
Lister, Joseph, 3085
Listeria monocytogenes, listeriosis, 525
Listeriosis
bacterial origins, 525
foodborne sources, 2039
pathology, 3084
Litchi tree, 3085
Lithification, defined, 3085
Lithium
alloy-metal sulfide battery, electric cars, 1722
aluminum-lithium alloys, 173
batteries, spacecraft power systems, 4924–4925
biological systems, 3086–3087
bromide, structure and properties, 810
hydroxide monohydrate, 3086
manic-depressive illness, 3232
molybdates, 3504
nomenclature and history, 1057
peroxide, 4007
structure and properties, 3085–3087
Lithium-ion power system, Space Technology 5 mission, 5076–5077
Lithofacies, defined, 1881
Lithography, electron beam, 1771–1774
Lithology, 3087
Lithometeor, 3087
Lithosphere
defined, 3087
of earth, 1630
polar regions, 4210
Little, Arthur D., 3087
Littoral, defined, 3087
Littrow prism, 4312
Lituus curve, 3087
Liver
adrenaline effects on, 72
diabetes mellitus physiology and biochemistry, 1485–1486
diseases of, 3088–3089
radionuclide scanning, 4412
familial hypercholesterolemia, 3087–3088
physiology and biochemistry, 3089–3090
structure and function, 3087
transplantations, 3090–3091, 5513
Liver abscess, 7
Livestock
foot-and-mouth disease, 2057–2059
Human Genome Project and, 2561
lice, 3113
Livestock safety index (LSI), 3091
Living with a star program (LWS), 3091–3094
Lizards
fossil history, 3099
habits and lifestyles, 3098–3099
phylogeny, 3099
swift, 5313
teju lizard, 5354
zoological classification, 3094–3100
Llamas, zoological classification, 860–861
Loaches, 3100
Load capacity, robotics, 4540–4541
Load cells, industrial scales, 5849
Load commutated inverter, direct current servo motors, 4741
Load factor, electric, 3100
Loading coil, 3100
Load matching, 3100
Loa loa infection, 1926
Lobachevskian geometry, 2221–2222
Lobe antenna patterns, 3100
Lobed-impeller flowmeter, 2005–2006
Lobsters, 1377, 1435
Local anesthetics, 234–235
Local apparent time, 3100
Local Area Augmentation System (LAAS), global positioning system and, 2289–2292
Local area networks (LANs)
automation and, 489
basic properties, 3100–3104
fiber optics technology in, 3811–3813
numerical control, 3721–3725
password systems and, 3969–3970
telephony systems, 5361–5362
wireless communications standards, 5912–5913
Local control, experimental design, 1477
Local telephone loop system, 5362–5363
Locomotion
in fishes, 1952
principles, 3104
Locusts, classification, 3104–3105
Locust tree, 3105
LODAR navigation system, 3598
Loeb, Jacques, 3105–3106
Loess
deposits, 3106
erosion, 1840–1841
Loewi, Otto, 3106
Löffler, Friedrich August Johann, 3106–3107
Lofting phenomenon, 3107
Log, navigational, 3108–3109
Logarithmic amplifier, 207
Logarithmic antenna, 256
Logarithms
basic principles, 3107
decrement, 3107
differentiation, 3107
e (transcendental number), 1848
function, 3107
iterated logarithms, 2836
scales, 4659–4660
spiral, 3107–3108
velocity profile, 3108
Logic
in computer systems, 3108
diagram, 3108–3109
resistor transistor logic, 4502
Logical calculi, automated reasoning, 358
Logical design, 3108
Logical instructions, digital computer systems, 1531–1532
Logic circuits
diode logic, 1550
diode transistor logic, 1550
Logic programming languages, 4324
automated reasoning, 359
Logistic curve, 3108
Logit variable, 3108
Log mean temperature difference (LMTD), 3108
Log-periodic antenna, 256
Logwood tree, 3110
Loma Prieta Earthquake, 1676–1677
London dipole theory, 3110
release agents, 4491
Longitude, geographic, 3110
Longitudinal rolls, 3110
Long-lived 50mK coolers, Beyond Einstein program, 617–619
Long range order, principles, 3110
Long-Range Rover (Mars), 3295
Long terminal repeats (LTRs), oncogene activation, 3792–3794
Long-term storage, food preservation, 2050–2051
Longwall mining, coal, 1181–1183
Long wave, definitions, 3110
Looming mirage, 3110–3111
Loons, zoological classification, 2197, 3111
Loop antenna, 256
defined, 3111
Loop configurations
computer system, 3111
mathematical, 3111
storage area networks, 5216
Loop currents (oceanic), 3760
Loop diuretics, 1578–1579
Loop gain
defined, 2152
feedback systems, 1889
Loop-Vee® antenna, 256
LORAC (long-range accuracy), 3110
LORAN (long-range navigation), 3110
A-station, 386
B-station, 820
radio systems for, 3597–3598
Lorentz, Hendrik Antoon, 3111
Lorentz equations, special relativity theory and, 4487
Lorentz force
earth's magnetotail, 1637
electromagnetic radiation, 1758–1760
Lorentz frame, 3111
Lorentz invariance, 3111
Lorentz transformation, 3111–3112
vectors, 5651
Lorisoids, 3112
Losser material, 3112
Loss factor, 3112
Loss function, 3112
Loss-in-weight feeder, gravimetric feeder, 1890
Loss-of-cooling accident (LOCA), nuclear power technology, pressurized-water nuclear reactors, 3698–3700
Loudness scales, 3112
physiological acoustics and, 32
Loudspeaker, structure and function, 3112–3113
Louse. *See* Lice

Lovebirds, classification of, 4348–4349
Low, meteorological, 3113
Low-bit-rate speech coding, 5742–5744
Low density lipoproteins (LDLs)
  cholesterol, 1088–1089
  diet and disease and, 1508–1509
Low density polyethylene (LDPE), food packaging systems, 2044
Low earth orbit (LEO), 3113–3114
  satellites, 4618–4620, 4624–4625, 4627–4629
Low-Energy Transmission Grating (LETG), Chandra X-ray Observatory, 1016
Lowest unoccupied molecular orbital (LUMO), organic light-emitting devices, 3844–3845
Low impedance piezoelectric accelerometer, conditioning for, 17–18
Low level detection techniques, trace and residue analysis, 5488
Low limiting control action, 1302–1303
Low-mass stars, Spitzer Space Telescope research, 5120
Low-pass filter, 1931–1933
Low power factor wattmeter, electric power measurement, 1727
Low-pressure storms, 2111
Lowry-Brønsted theory, acids and bases, 28
Low-shaft furnace, iron production, 2813–2814
Low-temperature hygrometry, 3114
Low-temperature materials, polycrystalline silicon liquid crystal display, 3069–3070
Low-temperature measurements, cryogenics, 1380
Low vacuum condition, 3114
Low-voltage air circuit breakers, 1116
L-S coupling, chemical elements atomic structure, 1040–1042
L-section, 3114
L stars, properties of, 5162
Lubricants and lubricating agents
  basic properties, 3114
  classification, 3115–3117
  grease, 2350
  naphthenic acids, 3576
Luciferins and luciferases, bioluminescence, 641–642
Ludwig, Carl Wilhelm Friedrich, 3117–3118
Luft balanced condenser microphone system, infrared detectors, 2709
Lumbar disk disease, bone pathology, 757
Lumber products. *See also* Pulp production and processing; Timber; Wood and wood products
  Douglas firs, 1947
  redwoods, 4470–4471
  wood composition and classification, 5922–5924
  wood-thermoset composites, 5921
Lumen unit, 3118
Luminance
  adaptation, 52
  brightness, 808
  directional luminous transmittance, 5509
Luminescence
  airglow, 104
  blue glow, 736
  classification, 3118
  electroluminescence, 1750
  excited state, 1865
  light-emitting diodes, 3118–3119
  pigments, 4111
  sonoluminescence, 4893
Luminosity
  candela unit, 872–873
  candle unit, 874
  coefficient, 3119
  distance, absolute magnitude and, 9
  efficiency, 3119
  in fishes, 1955
  flux, 2017
  function, 3119
  light-emitting diodes, 3029–3030
  mass-luminosity relation, 3335–3336
  period luminosity law, 4002
  reflectance, 4472
  stellar, 5190
  Yerkes spectral classification system, 5163
Lumped capacitance, 877
Lumped-constant wavemeter, frequency measurement, 2100
Luna 1–24 lunar missions, 3121–3122, 3124–3127, 3129, 3133, 3135, 3137–3141
Lunar-A mission, 3142
Lunar atmospheric tide, 459, 3119
Lunar eclipse, 1690, 1693–1694
  historical record of, 1694
Lunar exploration

applications using, 3187–3189
in biological systems, 3193–3195
chemistry and compounds, 3189–3193
deficiency, 3194
dietary sources, hypertension and, 1512
in fertilizers, 1908
nomenclature and history, 1057
nutrients, 3446
peroxide, 4007
production, 3187
sources of, 3187
titanium refining, 5467
Magnetically actuated dry reed switches, 4345
Magnetically levitated/propelled vehicles, 4439–4440
Magnetic amplifier, structure and properties, 207–208
Magnetic cooling, cryogenics, 1379–1380
Magnetic equator, 30
Magnetic fields
air gap, 104
Ampere's law, 196–197
comets, 1245–1246
core, 1329
cryogenics, 1380
defined, 3195, 3203–3204
dipole, 3195
electroacoustics, 36
galaxies and, 2155–2156
intensity, 1922–1923, 3195, 3203–3204
interplanetary medium, 2765
K-indices, 3196
lunar, 3151–3152, 3526
daily variation, 3196
on Mercury, 3377–3378
nuclear magnetic resonance/magnetic resonance imaging, 3689–3690
ordinary ray, 3828
Paschen-Back effect, 3963
plasma physics, 4159
quantum number, 4380–4381
remanence, 4493
retentivity, 4506
separation, 3203
susceptibility per unit volume, 3203–3204
variometer, 5650
Magnetic flowmeter, 2000–2003
Magnetic inclinometer, 1552
Magnetic ink character recognition (MICR), 3195–3196
pattern recognition, 3981
Magnetic materials
alloys, 3205
basic properties, 3204–3205
bulk, 3196–3197
cobalt in, 1203
disks, image archiving, 1541
Mars Exploration Rovers (Spirit and Opportunity), 3314–3315
molecular magnets, 3205
separation technology, 4731
tape storage, 3202–3203
thin films and particles, 3198–3199
thin film technologies, 5426
Magnetic moment
defined, 3199
neutrons, 3625–3627
Magnetic-particle methods, nondestructive testing, 3678
Magnetic probability switches, proximity and object detection, 4345
Magnetic refrigeration, 4482–4483
Magnetic resonance angiography (MRA), 3201
Magnetic resonance imaging (MRI)
basic principles, 3687–3690
brain imaging, 993
clinical applications, 3201–3202
coronary thrombosis, 1345
deep vein thrombosis/pulmonary embolism, 1444
medical imaging, 2651
pheochromocytoma, 64–65
primary hyperaldosteronism, 63
techniques and principles, 3199–3203
X-ray imaging and, 5949–5951
Magnetic storm, 3202
Magnetism and magnetization
antiferromagnetism, 277
Barkhausen effect, 559

circuits, 3204
definitions, 3203
diamagnetism, 1493
electromagnetic phenomena, 1756
ferrimagnetism, 1901
fluids
artificial, 3082–3083
dynamics, 2008
flux, 3204
Gauss units, 2196–2197
harmonic operation, 2391
induction, 2672, 3195, 3203–3204
isogonic line, 2831
magnetic moment, 3199
minerals, 3451
molecular magnets, 3205
paleomagnetism, 3909
paramagnetism, 3936
permeability, 4006
pressure, 3199
quantum effects and size, 3205
Stern-Gerlach experiment, 5207
Magnetite, 2806, 3205–3206
oceanic deposits, 3779
Magnetization curve, superconductivity, 5281
Magnetochemistry, defined, 3206
Magnetoconductivity tensor, electrical conductivity, 1713–1714
Magnetoelastic transducers, microwave acoustics, 36–37
Magnetoelectricity, 3206
Magneto generator, 3206
Magnetohydrodynamics
basic principles, 3207
earth geomagnetic field, 1634–1635
electromagnetic propulsion, 1766
frozen-in field, 2119
generator, 3206–3207
plasmas, 4158–4159
solar wind properties, 4878
Magnetoionic theory, 3207
Magnetometer
Advanced Composition Explorer (ACE), 78
Geostationary Operational Environmental Satellite (GOES) system, 2225
Lunar Prospector mission, 3151
Mars Exploration Rovers (Spirit and Opportunity), 3328
natural gas exploration, 3585
petroleum magnetic surveys, 4029
principles and components, 3207–3208
Magnetooptical rotation, 3208
Magnetooptic materials, 3198
Magnetopause, 3209
Magnetoresistance
electrical conductivity, 1713–1714
Hall effect, 2376
magnetic materials, 3198–3199
Magnetosphere
defined, 3209
on Jupiter, 2865
of Neptune, 3611–3612
of Saturn, 4648
on Uranus, 5615–5616
Magnetospheric Imaging Instrument (MIMI), Cassini-Huygens mission, 930
Magnetostatic theory, electromagnetic radiation, 1759–1760
Magnetostriction
defined, 3209
delay line, 1454, 3209
limit switch, 4346
Magnetotactic bacteria, 1637
Magnetotail, earth, 1637
Magnetron, microwave tubes, 3437
Magnetron amplifier, structure and properties, 208
Magnetron oscillator, 3209
Magnification
light microscopy, 3034
linear, 3050
magnifying power, 3209
optimum, 3820
Magnitude
absolute, 9–10
apparent magnitude, 305
earthquakes, 1670–1671
field strength and, 1923
order of, 3828
ratio
frequency response, 2101–2102
gain, 2152
Magnolia tree, 3209
Magpie, 3209
Mahagony tree, 3209–3210
Maidenhair tree, 3211
Maillard reaction, amino acids, 189
Major histocompatibility complex (MHC)
antigens, 285–287
cytokines and, 1418–1419
epitopes, 1833–1834
immune system and immunology, 2653–2655
threonine proteases, 4330–4331
thymus gland and, 5439
transplantation techniques, 5511
graft survival, 5514–5515
Maksutov-Bouwers telescope, 3211
Malachite, 3211
Malaprade reaction, 3211
Malaria
antimalarial drugs, 3213–3218
control of, 3213
epidemiology and pathology, 3211–3213
history of, 3211–3212
iron chelation therapy, 2812
preventive drugs, 3218
self-treatment medication, 3218–3219
Malarone, antimalarial drug, 3218
Malate, calcium, 849
Male germ unit, pollen development, 4215
Male hormones, 1809–1810, 2311–2315, 2507
infertility, 2681
Maleic anhydride, 4152
Maleo bird, 3219
Male pattern baldness, epidemiology and pathology, 156
Malic acid, 3219–3320
Mallophaga, 3220
Mallow plants, 3224–3225
Malnutrition. *See also* Diet; Nutrition
achlorhydria, 23
management of, 3221–3222
pathophysiology, 3220–3221
protein deficiency, 4333
starvation and, 5184
ulcers and, 5568
Malpighi, Marcello, 3222
Malt
beverages (*See also* Beer/malt beverages)
characteristics, 3222–3224
Maltha (coal), 3224
Maltitol
crystalline structure, 5302
properties and sources, 5252–5253
Maltose
structure and properties, 885, 3224
as sweetener, 5301
Malus cosine-squared law, 3224
Malvaceae, botanical classification, 3224–3225
Malvinas current, 3760
Mammals (mammalia)
cloning, 1152–1157
dolphins, 1584
edentata, 1699–1700
flipper in, 1988
gestation in, 2261
lorisoids, 3112
lymphatic system, 3158–3162
marsupialia, 3330–3331
monotremata, 3513
repellents against, 4496
sharks, 4759–4762
whales, dolphins, and porpoises, 5864–5866
zoological classification, 3225–3226
Mammography
breast cancer diagnosis, 865
x-rays in, 5949
Manakin bird, 3226
Manatee, 4687
Manganate
potassium, 4276
sodium, 4847
Manganese
in biological systems, 3229–3230
nomenclature and history, 1057
nutrients, 3447
oceanic nodules, 3780–3781
steelmaking, 2821
structure and properties, 3226–3229
todorokites, 5476
water treatment and removal of, 5788
Manganite, 3230
Mange mites, 3459–3460
Mangrove tree, 3230
Manhattan Bridge (New York), 802
Manhattan Project, 3230–3231
Manic-depressive illness, epidemiology and pathology, 3231–3232
Manifolds
differentiable topology, 5482
Lie group, 3022–3023
Manned Space Flight Network (MSFN), Apollo program, 4935–4937
Mannich reaction, 3232
Manning equation, 3232
Mannitol
manufacture of, 5254
properties and sources, 5250–5252
Manometers
absolute, 10
components, 3232
differential manometer, 1519
pressure measurement, 4307–4308
Manson, Patrick, 3232–3233
Mantis, 3233
Mantis fly, 3233
Mantle, of earth, 1632–1636
Manufactured abrasives, classification of, 6–7
Manufacturing
automation, 486
bakery processes, 543–544
foamed plastics, 2021–2023
glasses, 2273–2278
laser applications in, 2950–2951
naphthenic acids, 3575–3576
networks, 3615

Manufacturing (*continued*)
pharmaceuticals, 4046–4047
plasma physics, 4159–4160
tantalum parts in, 5339
Manufacturing Automation Protocol (MAP), 489
manufacturing message specification, 3233–3234
Manufacturing message specification (MMS), 3233–3241
device and object modeling, 3235
domains, 3236–3237
history, 3233–3234
ICCP-TASE.2 objects, 3235
program invocations, 3237
real and virtual devices and objects, 3234–3235
UCA objects, 3235
variable access model, 3237–3238
virtual manufacturing device, 3234
Many-body force, 3241
MAP kinases, cytokines, 1418
Maple syrup
evaporation technology, 3245–3248
filtration process, 3249–3250
packaging technology, 3250–3254
production, tapping, collection and storage, 3241–3245
standards for, 3251–3252
tree species for, 3254–3255
Maple tree, 3254–3258
Mapped images, 1928
Maps and mapping techniques. *See also* Genetics, linkage mapping; Geography; Projections; Topography

Margarines
classification, 5657
sorbic acids in, 4896
Margins, continental
ocean-continental boundary and, 3743–3745
ocean floor and crust, 3745–3746
Margules's equation, 3260
Marijuana
chemical properties and production, 3260–3261
hemp, 2444
Marine barometer, 3261
weather observations, 5833
Marine Biological Laboratory (Woods Hole), astrobiological research, 414
Marine biology
conchology, 1279
coral and coral reef formation and ecology, 1326–1328
crustacea/crustaceans, 1376–1379
dinoflagellata, 1545
echinodermata, 1688
echinoidea, 1688
entoprocta, 1819–1820
environment
whales, dolphins, and porpoises, 5865–5866
estuaries, 1845–1847
fluorine and, 2015
gastrotrichia, 2194
hemichordata, 2435
ocean life forms and balances, 3775–3776
venomous marine animals, 5663–5664
whales, dolphins, and porpoises, 5864–5866
Marine environments, basic properties, 1695
Marine pipelines, natural gas, 3589–3590
Marine rainbow, 3261
Mariner Missions
lunar rocks on, 3454–3455
Mars exploration, 3263–3268, 3274
Mercury, 3376–3378
solar system research, 4998
to Venus, 5670–5671
Mariotte's law, 780
Maritime air
aerosols, 3261
properties of, 105
Marjoram, 5105–5106
Marker systems, plant breeding and crop production, 4149
Mark-Houwink equation, 3262
Mark I computer, digital computer systems history and, 1528
Markov, Andrei Andreyvich, 3262
Markov chain, 3262
Markov equation, autoregression, 499
Markov process, 3262
Markownikoff rule, 3262
Marmoset, 3262
Marrow needles, shape-memory alloys for, 644–645
Mars
age determination, 3274
astrobiological research and, 406–415
atmosphere on, 3268–3270
characteristics of, 3262
climate of, 3270, 3273–3275, 3289
early "wet" Mars scenario, 3273–3274
exploration programs, 3262–3268, 3276–3283, 3288–3289
flybys, 3290
history of, 3292–3293
human exploration preparations, 3289–3290
Mars Exploration Rover Mission, 3302–3325
Mars Global Surveyor (MGS) mission, 3325–3329
Pathfinder Mission, 1557–1558, 3971–3980
Phoenix Mission to, 4057–4063
Russian exploration missions, 3285–3288
sample returns, 3292
satellites of, 3275
scientific goals, 3289–3290
subsurface explorers, 3291–3292
gravity, 3274–3275
Hubble Space Telescope images of, 2536–2538
life on, research about, 3289, 4059–4060
manned missions (proposed), 3276–3277, 4059–4060
natural laser phenomenon on, 3275
photography and imaging of, 4086–4087
polar behavior on, 3275
radar images of, 3275–3276
resources on, 4981–4982
satellites of, 4983
soil and rocks on, 3270–3271
space radiation on, 4972
terrain, 3271–3274
Viking Missions to, 3264, 3274–3275, 3277–3282, 5682–5687
volcanism, 3272–3273
weather on, 3270, 3275
"wet" Mars, 3273–3274
Mars Climate Orbiter, solar system research, 4998
Marsden chart, 3285
Marsden square, 3285
Mars Descent Imager (MARDI)
Mars exploration with, 3298
Phoenix Mission to Mars, 4062–4063
Mars Exploration Rovers (Spirit and Opportunity), 3294–3295, 3302–3325
cruise configuration, 3305–3306
entry, descent, and landing configuration, 330–3307
landing sites, 3303–3304
mission timeline, 3304–3305
Opportunity Mission highlights, 3318–3324
parachutes, 3307–3308
rover configuration, 3309
Rover egress phase, 3305
Spirit Mission highlights, 3315–3318
wheels and legs, 3312–3313
Mars Express/Analyzer of Space Plasmas and Energetic Atoms (ASPERA), solar system research, 4994
Mars Express mission, 3293–3294
Mars Global Surveyor (MGS) Mission, 3264
history of, 3292–3293, 3325
instrumentation, 3328–3329
solar system research, 4994, 4998
spacecraft, 3326–3328
aerobraking system on, 4905
technology, 3325–3326
Marsh, Othniel Charles, 3329
Marshall-Palmer relation, 3329
Mars Hand Lens Imager (MAHLI), Mars exploration with, 3298
Marshes
bioremediation, 678
cienega, 1111–1112
Mars Odyssey mission, 3293
solar system research, 4994
spacecraft design and instrumentation, 4905
Mars Orbiter Camera (MOC), Mars Global Surveyor (MGS) Mission, 3328
Mars Orbiter Laser Altimeter (MOLA), Mars Global Surveyor (MGS) Mission, 3328

Mars Pathfinder mission, 3265–3266
mechanical devices on, 4906–4907
solar system research, 4998
Mars Polar Lander mission, solar system research, 4998
Mars Reconnaisance Orbiter (MRO), 3295
solar system research, 4994
Mars Science Laboratory (MSL), 3296–3297
solar system research, 4995
Mars Surveyor '98 Lander mission, 3266–3267
Mars Surveyor '98 Orbiter mission, 3266
Mars Surveyor 2001 mission, 3267
Marsupialia, zoological classification, 3330–3331
Marten, zoological classification, 3556
Martensitic stainless steels
basic properties, 3331
chromium alloys, 1101–1104
Martin, Archer John Porter, 3331–3332
Martin (bird), 3332
Martingale paradox, 3332
Marvin sunshine recorder, 3332
Mascon (Moon), 3332

energy conversion, 3769, 3773–3775
equatorial deep jets, 3759
equatorial system, 1837–1838, 3757, 3759–3760
Florida current, 1996, 3760
gradient current, 2320
ground swell, 2359
Guiana current, 2362, 3760
Gulf Stream, 2363, 3760
Guyana current, 3760
gyres, 2369
Humboldt current, 2575
Irminger current, 2806
Kamchatka current, 3760
Kuroshio current, 3760
Labrador current, 2909, 3760
Langmuir circulation, 2925
La Niña, 2926–2928
Leeuwin current, 3760
Liman current, 3760
loop current, 3760
Malvinas current, 3760
meddies, 3358–3360
Mid-Japan Sea cold current, 3760
Mindanao current, 3760
Mozambique current, 3760–3761
New Guinea Coastal current, 3761
North Atlantic Current, 3761
North Brazil current, 3761
North Equatorial current/countercurrent, 3761
North Korea Cold Current, 3761
North Pacific Current, 3761
Norwegian current, 3761
Oyashio current, 3761
Peru/Chile current, 3761
Philippines Current, 3761
polar creep, 3757
Portugal Current, 3761
RAFOS technology, 3761
rip currents, 4529
salt fingering, 4612
Somali current, 3761–3762
South Atlantic current, 3762, 4900
South equatorial current/countercurrent, 3762, 4900
South Indian Ocean current, 3762, 4900
South Pacific current, 3762, 4900
subtropical countercurrent, 3762
surface currents, 3757, 3762
thermohaline circulation, 5419–5420
Tsushima current, 3762
turbidity currents, 3757
upwelling, 1198, 5601
West Australian current, 3762
West Greenland current, 3762
West-wind drift, 5857
Zanzibar current, 3762
Ocean Prediction Center, 5827

carbon, 889–891
carboxylic acids and anhydrides, 3834
cavitand, 959
chlorinated organics, 1078–1083
chromium organometallics, 1103–1104
classification, 3829–3831
clays, 3845
contaminants, bioremediation, 675–677
cyanohydrins, 1402
esters, 1845, 3835
ethers, 1848–1850, 3835
flocculating agents, 1989–1990
fluorine, 2014
fluorocarbons, 2016
Grignard reactions, 2356–2357
halogenated compounds, 3835
heterocyclic compounds, 3836–3837
homologous series, 2494
hydrocarbons, 3831–3834
imino compounds, 2652
insecticides, 2721–2724
kerogen, 2878
ketones, 3835
Kjeldahl test, 2899
nitrogen, nonheterocyclic, 3836
nomenclature, 3831
organoborane, 3845
organophosphorus compounds, 3845
organosilicon, 3846
organotin, 3846
paint and finish removers, 3896–3897
peroxides, 3835, 4011–4016
phosphorus, 4068–4069
pigments, 4112–4115
polymers, 4252–4253
radioprotective agents, 4429–4432
roofing materials, 4563
semiconductors, 4718–4722
sensitizing dyes, 1620
sulfur
biological systems, 5267–5269
nonheterocyclic, 3836
thiols, 5429–5430
tin, 5457–5459
titanium, 5470
volatile organic compounds, 5744–5745

Organic farming, fertilizers and, 1907
Organic light-emitting diodes (OLEDs)
microdisplays, 3421
molecules, 3844–3845
monochromatic devices, 3843–3844
structure and properties, 3842–3843
Organismal senescence, gerontology and, 2256
Organoborane, 3845
Organ of Corti (ear), 2398
Organometallic compounds
basic properties, 3845
germanium, 2254
inorganic chemistry and, 2713
mercury, 3375
molybdenum, 3504
titanium, 5470
Organosols, 3846
polyvinyl chloride, 4259–4260
Organs, transplantation
immunogenetics and, 2662–2663
kidney transplants, 2890
liver, 3090–3091
pancreatic transplantation, 1489–1490, 3918
survival data, 5513–5514
techniques and requirements, 5511–5514
tissue engineering, 5461–5462
Organs (biological), 3829
lymphoid organs, 5630
organogeny, 3845
trichome specificity (plants), 5525–5526
Oriental fruit fly, 2124
Oriental fruit moth, 3846
Oriented adsorption, defined, 76
Oriented polypropylene (OPP), food packaging systems, 2045
Oriented Scintillation Spectrometer Experiment (OSSE), Compton Gamma-Ray Observatory (CGRO), 1262–1264
Oriented strandboard (OSB), wood-thermoset composites, 5920
Orifices
classification and function, 3846
differential-producing flowmeters, 1999–2000
Origins program
ground-based observatories, 3851–3852
missions, 3848–3851
overview, 3846–3847
scientific goals of, 3847–3848
Spitzer Space Telescope, 5111
Oriole (bird), 3852
Orion Crew Exploration Vehicle, 3852–3858
Orion star cluster, Chandra X-ray Observatory images, 1018–1020
Orion (the hunter) (constellation), 3857
Orleans process, viinegar processiong, 5688
Ornithine cycle, 5617
Ornithology, defined, 3857
Orogeny
Allegheny orogeny, 146
Alpine orogeny, 157
biogeography, 637–640
principles, 3857
Orography, precipitation, 4301
Orpiment, 3857–3858
Orthoclase, structure and characteristics, 1895–1896
Orthogonal antennas, 3858
Orthogonal function, mathematics, 3858
Orthographic projection, 3858–3859
perspective, 4017–4018
pictorial representation, 4106
Ortho-hydrogen, 2591
Orthokeratology, 3859
Orthokinetic flocculator, water clarifiers, 1122–1124
Orthomyxoviruses, replication, 339
Orthopedic devices, biomaterials, 644–645
Orthophosphates, urea-ammonium, 5618
Orthophosphoric acid, in fertilizers, 1907–1908
Orthopnea, congestive heart failure, 1283
Orthoptera, 3859
Orthoscopic system, 3859
Orthotomic system, 3859
Osborn, Henry Fairfield, 3859
Oscillating disks, viscosity properties, 5705
Oscillating doublet antenna, 256
Oscillating-piston flowmeter, 2005
Oscillations
basic principles, 3859–3860
center of, 977
flutter, 2017
gravity wave, 2349
lakes, 2913–2914
librations, 3021
Madden-Julian oscillation, 3183
phugoid oscillation, 4098
plasma and plasma frequency, 4165
Oscillators
balanced, 547
components and instrumentation, 3860
coupled oscillator, 1361–1362
crystal oscillator, 1391
fluidics of, 2011–2012
frequency divider, 1573, 2099
phase-shift, 4053
Pierce oscillator, 4106
Rieke diagram, 4526
signal processing and transmission, 4771
tuning fork, 5551
Oscillatory flowmeters, 2002–2003
Oscillometry, 3860–3861
Oscilloscope
components of, 3861
frequency measurements, 2099
Osculating orbit and plane, 3861
Oseltamivir, 300
Osmium
nomenclature and history, 1058
in platinum group, 4170–4171
structure and properties, 3861–3862
Osmosis, defined, 3862
Osmotic coefficient, 3862
Osmotic diarrhea
carbohydrate metabolism, 887–888
epidemiology and pathology, 1498
Osmotic diuretics, 1574
Osmotic pressure
basic properties, 3862–3863
blood, 722–723
organic polymers, 4252–4253
potassium, 4277–4278
saline gradients, ocean energy conversion, 3773–3775
water metabolism, 5785
O stars, properties of, 5161
Osteichthyes (fishes)
behavior, 3865–3866
classification, taxonomy and characteristics, 1948–1956
diversity and fossil record, 3864
habitats and abundance, 3864–3865
phylogeny, 3863–3864
zoological classification, 3863
Osteitis deformans. *See* Paget's disease
Osteoarthritis
epidemiology and pathology, 3866
thiophene/thiophene derivative therapies, 5431
Osteology, 3867
Osteomalacia, pathology, 757
Osteomyelitis, pathology, 756
Osteopetrosis, pathology, 757
Osteoporosis
calcium supplementation, 851–852
pathology, 756–757
Ostrich, characteristics and classification, 3867–3868
Ostwald, Wilhelm, 3868
Ostwald coefficient, gas sollutions, 4886
Otitis externa, 2399
Otitis media
acute, 2398–2399
chronic, 2399
Otosclerosis, deafness and, 2400
Otter, zoological classification, 3556
Outbreaks, foodborne diseases, 2032–2033
Outcroup, geologic, 3868
Outgassing, 3868
on Venus, 5669
Output reading, reference accuracy, 19
Output unit (computer systems), 3868
Ouzel bird, 3868
Oval of Cassini, 3868
Ovaries
cancer of, 866
endocrine system and endocrinology, 1809–1810
structure and function, 2312–2313
tumors of, 2313
Overcast sky, 3868
Overfold, geological, 3868
Overhead transmission technology, electric power production and distribution, 1738–1740
Overlap, definitions, 3868
Overlay networks, telephone switching systems, 5370
Overload, gas turbine configuration and, 2189
Overseeding (clouds), 3868–3869
Overthrust, 3869
Overvoltage, 3869
Oviparous reproduction, 3869
Ovipositor, 3869
Ovoviviparous reproduction, 3869
Ovules (botanical), carpels, 915–917
Owen, Richard, 3869
Owen bridge circuit, 797–798
Owens dust recorder, 3870
Owls, 3870
classification, 5222–5223
Oxalates
ammonium compounds, 194
calcium, 849
cobalt, 1204
food toxicants, 2055
lead, 3001
magnesium, 3191
oxalic acid derivatives, 3871–3872
sodium, 4847
strontium, 5227
Oxalic acid
basic properties, 3870–3871
derivatives, 3871–3872
reactions, 3870
Oxamides, 3871–3872
Ox bow lakes, 3872
Oxidation
actinides, 45–46
amino acids, 189
anodic, 247
autolysis, 484
autoxidation, 500

Oxidation (*continued*)
basic principles, 3872
biological, 630–631
catalysts, 941
chemosynthesis, 1069
chromium, 1102–1104
germanium compounds, 2253–2254
Jones oxidation, 2855
lignite and brown coal, 3045
number, 3872
oxidation-reduction reactions
chemical equations for, 1062–1063
indicators, 3872
mechanisms of, 3838–3839
potential, 3872
sugar alcohols, 5253
tropospheric ozone, 3879, 5538–5539
vanadium, 5641–5642
vinyl chloride, 5690
Oxidative cleavage, 3838
Oxidative-coupling, polymerization, 4246–4247
Oxidative degradation, antioxidants, 293–294
Oxidative fermentation, 1897
Oxidative phosphorylation, 4071–4072
Oxide fuel cells, 2129–2130
Oxides
antimony, 291, 1960
arsenic, 326
basic, 567
bromine, 811
cadmium, 846
calcium, 849
chlorine, 1085
chromium, 1103–1104
cobalt, 1203
copper, 1324
electrical conductivity, 1713–1714
germanium compounds, 2253–2254
hydrated titanium, 5470
iodine, 2785–2786
magnesium, 3191–3192
manganese, todorokites, 5476
mercury, 3374
molybdenum, flame retardants, 1961
nitrogen, 3662
air pollution and, 4229–4230
oxygen, 3874–3875
phosphorus, 4067–4068
refractory materials, 4478–4479
strontium, 5227
sulfoxides, 5258
sulfur, air pollution and, 4229
tantalum pentoxide, 5340
thorium, 5434
tin, 5456
uranium, 5605–5606
vanadium, 5643–5644
zinc, 5975–5976
zirconium, 5980
Oxidizing materials, 3872
Oximes, 3872
Oxo ion salts, uranium and, 5606–5607
Oxonium compounds, 3872–3873
Oxo process
alcohols, 129, 211–212
history and applications, 3873
Oxoreductases, classification, 1826
Oxyacids, 3873
phosphorus, 4067–4068
Oxyazo compounds, 3873
Oxychlorination, catalysts, 941
Oxygen
absorption bands, 11
allotropic forms, 3874
balance, 3877
cell, 3877
corrosion from, 1348–1349
cosmic water, 1352–1354
debt, 3877
demand and consumption, 3877
dissolved oxygen, 1568
Earth's supply of, 3876–3877
environmental impact, 3876
feedwater system control of, 1894
fluorine and, 2014
group, 3877
industrial applications, 3875
iodine and, 2785
ions, coordination polyhedra, 1319
isotopes, paleoclimatology and, 3905–3906
on Moon, 4980–4981
nitrification and, 3657
nomenclature and history, 1058

    stroke pathology, 5224–5225
  physiology of, 3936
  quadriplegia, 4370
  tabes dorsalis, 5331
Paramagnetic amplifier, 209
Paramagnetic contrast agents, magnetic resonance imaging, 3200–3201
Paramagnetism, basic characteristics, 3936
Parameterization
  defined, 3936
  Mellor-Yamada parameterization, 3365
  shallow convection parameterization, 4752
Parameters
  properties of, 3936
  statistical, 3936
Parametric acoustic array, microwave acoustics, 37
Parametric equations, 3936
Paramyxoviruses, mumps, 3549
Paraphase amplifier, 209
Parapoxviruses, 4296–4297
Parasites
  African trypanosomiasis, 92–93
  anglerfishes, 241
  as beneficial insects, 601
  curculios, 1394
  defined, 3936
  dermatitis/dermatosis, 1468–1469
  filiariasis and, 1925–1926
  fish louse, 1956

Parasites (*continued*)
flukes, 2012
foodborne diseases, 2030, 2033–2039
food toxicants, 2057
giardiasis, 2264
guinea worm, 2363
host, 2514
hydatid disease, 2758
intestinal parasites, nematodes, 2767–2771
lice, pediculosis infestations, 3987–3988
mites, 3459–3460
parasitism, 5316
phylloxeran, 4098
pinworms, 2770–2771, 4122
plants, 3936
root systems, 4566–4568
scale insects, 4661–4663
tapeworms, 5341
theileriasis, 5406–5407
toxoplasmosis, 5487
trypanosomiasis, 92–93, 5540–5541
tsetse fly, 5541
vaccine research against, 5628–5629
Parasitology
classification system, 3937–3939
historical background, 3936–3939
tropical parasitology, 3938–3939
Parasol satellite mission, 4987
Parasomnias, classification, 4815–4817
Para-state, 3939
Parastillation, 1571
Parathyroid glands
anatomy and diseases of, 3939–3940
endocrine system and endocrinology, 1809–1810
hormones in, 2502–2507
Paratyphoid fever, foodborne transmission of, 2033
Parcel (fluid), 3940
Parcel testing method, 3940
Parenchyma
boundary parenchyma, 3941–3942
distribution, 3941
glossary of terms, 3943
ground tissues, 4137–4138
ontogenic development, 3943
plant cells, stems, 5192–5193
structure and classification, 3940–3943
synthetic, 3941
transport and storage, 3942
Parenchymatous hemorrhage, 1005
Parenteral dosage forms, drug manufacturing, 4048
Paresthesia, physiology of, 3943
Pareto chart, statistical quality control, 4374
Parhelia
altocumulus clouds, 1165
atmospheric halos, 464
Parity bit, 707
Parity checks, information theory, 2693–2694
Parkes process, 3944
Parkfield experiment in earthquake forecasting, 1678
Parkinson's disease
brain involvement in, 783
clinical presentation, 3945
epidemiology and pathology, 3944–3945
glossary of terms, 3946–3949
neurochemistry, 3944–3945
pathophysiology, 3945–3946
stereotactic surgery, 3946
treatment, 3945
Parotitis. *See* Mumps
Parrots, 3949–3950
classification of, 4347–4349
Parr turbidimeter, 5557
Parsec unit, 3950
star size classification and, 5157–5161
Parseval's theorem, 3950
Parshall flumes
flow measurement and control, 2006
structural properties, 2012
Parsley, 5106
Parthenogenesis, 3950
Partial correlation, 3950
Partial differential equation (PDE)
basic principles, 1518–1519
classification of, 3950–3951
field theory, 1923–1925
Partial integration, 2743–2744
Partially balanced incomplete blocks, 3951
Partial-oxidation gasification, substitute natural gas production, 5242
Partial pressure, 3951
defined, 4308
Partial-pressure analyzers, vacuum system, 5638
Particle accelerator, 3951
subatomic particle physics, 3956–3957
Particle agglomerators, diesel engines, 1506
Particle beam fusion technology, fusion power research, 2148
Particleboard, wood-thermoset composites, 5920–5921
Particle deposition
acid rain and, 25
corrosion from, 1348–1349
Particle dispersion, 1564
Particle-field interactions, plasmas, 4158–4159
Particle generators, subatomic particle physics, 3957
Particle physics. *See also* Subatomic particles

spark chamber, 5088
stopping power, 5214
tau particle, 5348
upsilon particle, 5601
virtual work, 5927
Particles and particulate matter
air pollution, 4226–4228
air pollution and, 4220, 4226–4228
cloud classifications and, 1163
cloud formation and, 1162–1163
defined, 3962
definitions of, 3951
interstice, 2767
magnetic materials, 3198
phonons, 4064
precipitates, 4299
in Saturn's rings, 4645–4648
sedimentation and, 4702–4704
solar energetic particles, 4862
solvent casting/particulate leaching (SCPL), tissue engineering, 5463
velocity, 3962
Particle size
definitions, 3951
dietary fiber, 1510
ion-exchange resins, 2791
liquid-solid extraction, 1874–1875
pigments, inorganic, 4110–4112
separation technologies, 4732–4733
Particle system model, computer animation, 1271–1273
Partition
definitions, 3962
function, 3962
Partridge, 3962
Parts per billion (PPB), 4298
Parts per million (PPM), 4298
Party lines (telephone), 5362–5363
Parvoviral enteritis, 3962
Parvovirus B19, sickle cell anemia, 231
Pascal, Blaise, 3962
Pascal's law, hydrostatics, 2611–2612
Pascal's snail, 3046
Pascal triangle, 3962–3963
probability and, 4314
Pascal unit, 3962
Paschen, law of, 3963
Paschen-Back effect, 3963
Passeriformes, zoological classification, 3963–3965
Passive atmospheres, rare gases in, 4456
Passive design techniques
nuclear power reactors, 3709–3713

solar energy heating and cooling, 4866–4867
Passive network, 3965
Passive simulation, computer animation, 1272–1273
Passive transducer, 5494
Passive vaccine, 5625–5626
Passivity, iron, 3965
Passwords, computer systems, 3965–3970
Pasteur, Louis, 3971
vaccination and, 5625
Pasteurization, 3971
Patch-clamp technique, ion channel separation, 987–988
Patch (computer systems), 3971
Patched conics, spacecraft guidance, navigation and control, 4916
Patent ductus arteriosus, 2406
Patenting, steels, 2823
Patent log, 3971
Patents, trademarks and, 5492
Pathfinder Mission to Mars, 3971–3980
cruise configuration of, 3972–3973
entry, descent and landing phase, 3973–3976
instrumentation, 3976–3977
lander site location, 3978–3979
Pathogenesis, defined, 3980
Pathogenic bacteria, structure and classification, 514
Pathological anatomy, 226
Path train, 3971
Pathway reactions, 3980
Patina, definitions, 3980
Patternation, spray droplets, 5133–5135
Pattern recognition
machine vision, 3176
principles of, 3981
Patterson function, crystallography, 1385
Pattinson process, 3981
Patulin, toxicology, 3565–3566
Pauli, Wolfgang Ernst, 3982
Pauli exclusion principle
binding energy, 624–625
chemical elements, atomic structure, 1039–1042
defined, 3981
quantum mechanics and, 4379–4380
solid-state physics and, 4882
Pauling, Linus Carl, 3981–3982
Pauling scale electronegativities, 1775
Pavement cells, epidermis (plant), 1830
Pavlov, Ivan Petrovitch, 3982–3983
Pavlov's conditioned reflex, memory function, 993
Pawpaw tree, 2993
PCS standards, wireless communications, 5909
Peach tree, 4578–4579
Peach tree/twig borers, 762, 3983
Peafowl (peacocks), 3983–3984
Peak demand and energy forecasts, electric power and distribution, 1730–1741
Peaking circuit, 3984
Peaking transformer, 3984
Peanut-groundnut, 3984–3985
Pearl, 3984
Pearlite, steels and steelmaking, 2819
Pearson, Karl, 3985–3986
Pearson distribution, 3984–3985
Pear tree, 4579
Pear tree borer, 762
Peat/peat coal
basic properties, 1176–1177, 3986
waxes from, 5814
Pea weevil, 3986
Pebble mills, 552, 3987
Pecan trees, 2472–2473
Peclet number, 3987
Pectic substances, food additives, 2028–2029
Pectinases, catalysts, 941
Pectins, 3987
in diet, 1509
Pectocelluloses, 971
Pedersen, Charles John, 3987
Pediculosis, infestation and management, 3987–3988
Pedigree analysis
genetic linkage mapping, 2206–2207
genetics and, 2207
hemophilia, 2438
Human Genome Project research on, 2548
inbreeding, 2667
Pedology, 3988
Pedunculopontine nucleus (PPN), Parkinson's disease and, 3945–3946
Peer-to-peer mechanism, programmable controller communications, 4323
Pegasus (constellation), 3988
Pegasus launch vehicle, 2958–2959
Pegmatites
economic and industrial applications, 3453
minerals, 3452, 3988
Pelagic deposits and ooze, ocean floor and crust, 3746
Pelecaniformes, 3988–3989
Pele's hair (lava), 3989
Pelicans, 3988–3990

Primary cells
tissue engineering, 5463
viral structure, 5700
Primary circulation, 4310
Primary hyperaldosteronism, 62–64
Primary hypertension, 2626–2627
Primary irritant dermatitis, allergic reactions, 150
Primates, zoological classification, 4310–4311
Prime meridian, 4310
Primers, enzymes, 1823
Priming, memory function, 992
Priming (drugs), radioprotective agents, 4430
Primordial heat hypothesis, earth's core, 1635
Principal component analysis, 4310
Printed circuit boards (PCBs)
basic properties, 4311–4312
bismaleimide polymers, 705
integrated circuits, 2738–2739
Prions
bovine spongiform encephalopathy pathology and, 772–777
classification, 516
Creutzfeld-Jakob disease, 1366–1367
Priroda space station module, 5051, 5054
Prism
binocular, 625
mathematical, 4312
objective, 3738
optical, 4312–4313
Private branch exchange (PBX), telephony systems, 5361–5362
Probability
defined, 4313–4314
integral, 4314
transition probability, 5499
Probability density function, 4314
Probability distributions
cumulants, 1394
defined, 4314
density distributions, chemical elements, atomic structure, 1042
range of probability, 4448
Probable error, 4314
Probenecid, gout, 2318–2319
Probiotics, 4314–4315
Problem-oriented languages
computer systems, 2926
digital programming, 1533–1534
Proboscis, 4316
Procainamide, 325
Procedure-oriented language, 2925
Procellariiformes, 4316
Process-activating proteins, chemistry of, 4335
Process analyzers
mass spectrometers as, 3337–3338
statistical quality control, 4374–4375
Process annealing, cold-worked metals, 244–245
Process control systems, 4316
valves, cavitation, 960
Process gas chromatography, 1099–1100
Process industries, statistical quality control, 4375
Process management and monitoring
control systems, 1309–1310
digester, 1523
evaporation, 1856–1858
for sweeteners, 5310–5311
Processors, digital computer systems, 1535
Process planning, computer-aided manufacturing, 491
Proctective anatomy, of fishes, 1952–1953
Proctitis, 4316–4317
Procyon (star), 4317
Producer's risk, statistical quality control, 4375–4376
Product, mathematical, 4317
Productivity, automation and, 485–492
Product modulator, 4317
Product-moment, 4317
Profile, definitions, 4317
Progesterone
classification of, 5210
structure and classification, 2503–2507
Progestins, classification of, 5210
Program amplifier, 209
Programmable controller (PC)
communications, 4321–4323
components, 4319–4320
defined, 4317
functions, 4318–4319
historical background, 4317–4318
input/output systems, 4320–4321
Programmable logic controller (PLC), 4318
Programmable read-only memory (PROM), classification, 3368
Program register, 4484
Programs and programming (computer)
algorithms, 138
defined, 4317
digital computer systems, 1532–1534
flowchart, 4323
FORTRAN programming, 2068
languages, 4323–4324
linear programming, 3050–3051
relocation, 4325
robotics, 4539–4540
software and software engineering, 4852–4853
translators, 5500–5501
Program verification and synthesis, automated reasoning, 359
Progression, definitions, 4325
Progressive multifocal leukoencephalopathy, 4325
Progressive wave, 4325
Progress-M Cargo Transport, Mir space station, 5051–5054
Projection clock, 1149
Projection radiography, 5944–5947

direction of, 4326
infrared radiation, 2707
pineapple, 4118
polymerization reactions, 4245
radical polymerization, 4247–4248
radio energy, 4422
Propagation velocity, 1702
Propane gas, 4326
Propellants
Cape Canaveral testing facilities for, 4958
on Mars, manufacture of, 4981–4982
rocket propellants, 4545–4548

rocket propulsion theory, 4551–4554
Propellers
design and structure, 110–111
fans, 1885
Proper motion of stars, 4326–4327
Prophase, cell division, 967
Prophylactic vaccine, 5656
Propionibacterium acne, 30
Propionic acid/propionates, food processing, 289
Propolis, 4327
Proportional controller
action, 1302–1303
structure, 1304
Proportionality, Kolmogorov constant, 2903
Proportional limit, 4327
Proportional plus derivative controller
action, 1303
structure, 1304
Proportional plus integral controller
action, 1303
structure, 1304
Proportional speed floating controller, 1989
Propranolol, 325
catecholamine effects, 70–72
Proprioceptive stimulation, 4327
Propulsion systems
airplane design, 110–114
electromagnetic, 1760–1768
high-speed rail, 4439–4440
jet propulsion, 111–114
Mars Global Surveyor (MGS) Mission, 3327
rocket propulsion theory, 4548–4554
spacecraft design planning and, 4904–4905, 4909–4910
Space Technology 5 mission, 5078
Stardust Mission, 5182
Propulsive efficiency, basic principles, 111–112
Propylene oxide, styrene manufacture, 5232
Prorenin, nephropathy, diabetes mellitus, 1487
Prosopagnosia, memory function, 992
Prostaglandins
composition and function, 4327
radioprotective agents, 4431
Prostate gland, cancer of, 866
Prosthetics
artificial skin, 832
biomaterials, 642–645
Prosthetic valve endocarditis, anticoagulant therapy, 276
Protactinium
nomenclature and history, 1059
structure and properties, 4327–4328
Protease inhibitors
HIV targeting, 300
as radioprotective agents, 4430
Proteases
aspartic, 4331
blood coagulation and, 731–732
catalysts, 941, 4328–4330
classification, 4328–4332
cysteine, 4331
families and clans, 4329
functional activity, 4328
metalloproteases, 4331–4332
serine protease, 4329–4330
threonine proteases, 4330–4331
Protected-membrane roofing technology, 4563
Protective systems, natural rubber vulcanization, 4593
Protein C, blood coagulation, 734–735
Protein kinase C, alcoholism, 127
Proteins
basic properties, 4332
blood coagulation, 731–732
chemistry of, 4335–4339
clotting mechanism and structure of, 729
collagen, 1221
cytokines, 1417–1419
deficiency, 4333
diet recommendations, 1507
efficiency ratio, 4337–4338
food toxicants, 2054–2055
glycosylation, diabetes mellitus and, 1491
histamines, 2479–2481
histones, 2482–2483
Human Genome Project research on, 2546
hydrolysates, 4332
industrial biotechnology, 2673–2674
keratin, 2876
malnutrition, 3221
in milk, 3440–3441
muscle fiber, 3550
neuron membranes, 986–987
neurotransmitters, 3621–3623
nutrition and, 3725–3726
polypeptides, 4255
proteases and, 4328–4332
quality and evaluation, 4337–4338
requirements for, 4332–4333
sources of, 4333–4335
in soybeans, 4901
structural genomics and, 5229–5230
vegetable oils, 5657
zein, 5959
zinc finger, 5976–5977
Proterozoic era, 4340
Protium, 4340
Protocellular processes, astrobiological research, 412–415
Protocol stacks, transmission control protocol/internet protocol (TCP/IP), 5502
Protocomet body, 1244
Proton-K launch vehicle, 2980–2982
Proton-proton reacation, 4340
Protons
binding energy, 624
Compton effect, 1260
diprotons, 1553
radioactivity of, 4407
structural properties, 4340
subatomic particle physics, 3952–3953
Protostellar phase, star formation, 5152
Protozoa
autogamy, 482
classification of, 4340–4342
giardiasis, 2264
intestinal parasites, 2771–2772
malaria pathology and, 3213
microbiology, 3415
noctiluca, 3668
paleontology, 2780
stigma, 5211
toxoplasmosis, 5487
trypanosomiasis, 92–93, 5540–5541
Protractor, 4341
Proustite, 4341
Provitamin, 4342
Proxima Centauri (star), 5153–5154
Proximate analysis, coal testing, 1186–1188
Proximity, object detectors and, 4342–4346
Pruritis, 4346
Pseudoadiabatic process
atmosphere, 450
defined, 4346
expansion, 4346
lapse rate, 4346
Pseudocode, 1208–1209
Pseudoelastic devices, shape-memory alloys, 4755–4756
Pseudoequivalent potential temperature, 4346–4347
Pseudoesotropia, 1844
Pseudofolliculitis barbae, 2027
Pseudoinstruction, computer systems, 2729
Pseudomembranous enterocolitis, diarrhea and, 1499
Pseudomonas folliculitis, 2026
Pseudomonas putida, waste management applications, 5779
Pseudomorphism, minerals, 3452, 4347
Pseudoplastic structures
colloids, 1224
rheology, 4516
Pseudopotential theory, chemical elements, 1051
Pseudorandom noise (PRN) signal, global positioning system and, 2285–2287
Pseudoscalar quantity, 4347
Pseudoscorpion, 4347
Pseudovector, 4347
multiplication, 5652
Psilocybin, 2380–2381
Psilomelane, 4347
Psi particle, 4347
Psittaciformes, classification and properties of, 4347–4349
Psittacosis, pathology of, 4349–4350
Psoriasis, 1470–1471
Psychological acoustics, 32–36
Psychological testing, chronic fatigue syndrome diagnosis, 1106–1107
Psychology and psychological disorders
alienation coefficient, 139
attention-deficit-hyperactivity disorder, 2621
eating disorders, 1683–1685
manic-depressive illness, 3231–3232
mood disorders, 3517–3520
schizophrenia, 4675
Psychrometer/psychometric chart, 4350–4351
Psychrometry
definition and applications, 2617–2620
hydrodeik psychrometer, 2585
psychrometric chart, 2617
Ptarmigan, 4351
Pteropsida, 4351
Pterosaurs
anatomy and morphology, 4352
life styles and diversity, 4352
paleological classification, 4351–4352
Pterygota, 4353
Ptomaine, 4353
Ptosis, 1879
Ptyalin (saliva enzyme), 1524
Puberty, adolescence and, 59
Public switched telephone network (PSTN)
modems, 3473–3477
telephony, 5358
Puccinia gramnis, botanical classification, 2138
Puffer fish
classification, 4353
poisoning, 2038
Pulleys, simple machines, 3174
Pulmonary disease
actinomycosis, 47
cryoptococcosis, 1381
hemoptysis, 2440
pneumonia, 4180–4182

Pulmonary disease (*continued*)
pulmonary embolism, 5437
anticoagulant therapy, 276
computed tomography, 1266–1268
epidemiology and pathology, 1443–1444
pathology, 331
stenosis, 2406
Pulp production and processing
hemicelluloses, 2434–2435
overview, 4353–4354
paper and paper products, 3922–3928
pulp bleaching, 714
pulp classification, 4354
recycling/regeneration, 5779–5780
refining, 4356
screening and washing, 4356
tall oil, 5334–5336
wood chip preparation, 4354–4356
Pulsars
basic properties and classification, 4356–4357
Compton Gamma-Ray Observatory (CGRO), 1263
Rossi X-ray Timing Explorer (RXTE), 4584
Pulsation, burners, 833
Pulse
compression, 4357
definitions, 4357
generator, 4357–4358
integration, 4358–4359
length, 4359
modulation, 4359
radar, 4359
volume, 4359
Pulse code modulation (PCM)
earth-orbiting satellites, data receiving and handling facilities, 1658–1663
fiber optics technology, telephony and, 5364–5366, 5368
quantization, 4377
speech coding, 5742–5744
telephony switching systems, 5368–5370
global telephone networks, 5370–5371
Pulsed alternators, electromagnetic propulsion, 1765
Pulsed field gel electrophoresis, 1782
Pulse-echo gauges, 5424
Pulse-jet engine, 4359
Pulse-pair processing, 4359
Pulse radar, chirp, 1076
Pulse-width modulated (PWM) drives, direct current servo motors, 4743
Pultrusion, 4359
Pulverized coal burner systems, 834–835
Pumas, zoological classification and characteristics, 953
Pumice, 4359
Pumped-storage plants, hydroelectric power, 2588–2589
Pumping proteins, neuron membranes, 986–987
Pumps and pumping systems
liquid, 4359
trap, 5516
vaccuum systems, 5634–5636
windmills, 5883–5884
Punctuated equilibrium, evolution and, 1863
Punctured eardrum, 2399
Punkie (midges), 4359
Punnett, Reginald Crundall, 4359–4360
Pupa, 4360
Puppis (constellation), 4360
Purchasing systems, intranets, 2772–2773
Pure-tone audiogram, hearing and sound measurement, 2400–2401
PUREX fuel processing, uranium, 5604
Purga (wind), 719
Purification systems
ion-exchange resins, 2798
magnetic separation, 4731
Purines
adenine, 56
gout, 2318–2320
neurotransmitters, 3619, 3621–3623
structure and function, 4360
Purkinje system
heart and circulatory system, 2403
Purkinge effect, 4360
Purofer process, iron production, 2814
Purple light, 4360
Purpura disorders, 4360
Push-pull amplifier, 209–210
power supply, 4293
Pustule, 4360
Pycnogonida, 4360
Pycnometer, 4360–4361
Pyogenic osteomyelitis, 756
Pyramid, structural properties, 4361
Pyranometer, structure and function, 47
Pyrargyrite, 4361
Pyrgeometer, structure and function, 47
Pyrheliometers
basic properties, 4361
Eppley pyrheliometer, 1836
structure and function, 47
Pyridazinones, 2457
Pyridines
applications, 4362–4366
herbicides, 2457
production of, 4362
structure and nomenclature, 4361–4362
Pyridinol carbamate, 4365
Pyrite, 4366
Pyrithione, 4365
Pyrithioxin, 4365
Pyroclastic, 4366
Pyrogenetic minerals, 4366
Pyrogenic silicas, 4776–4778
Pyrolusite, 4366
Pyrolysis
basic principles, 4366
clean coal conversion and, 1191–1195
waste as energy and, 5781–5782
Pyrometers/pyrometry
basic properties, 4366–4367
optical, 3819, 4402–4403
pneumatic-probe pyrometer, 4179
pyrometric cones, 4367
Pyromorphite, 4367
Pyron unit, 4367
Pyrophoric material, 4367
Pyrophosphate, stannous, 5457
Pyrophosphoric acid derivatives, insecticides, 2724
Pyrophyllite
basic properties, 4367
clays, 1128
Pyrotechnics
basic principles, 4367
flare, 4367
Pyroxene, 4367–4368
Pyroxidine, 5733–5734
Pyrrhotite, 4368
Pyrroles, 4368
Pyrrolopyrroles, pigments, 4114
Pyruvic acid, anaerobic acidation, 886
Pythagorean scale and theorem, 4368
Q fever, 4526
QRS complex, electrocardiography, 1744–1745
Quadrant, surveying and astronomical applications, 4369
Quadratic equation, 4369
Quadrature
astronomy, 4369
differential equation, 4369
Quadrature amplitude modulation (QAM), modem equipment, 3475–3477
Quadric surface
defined, 4369–4370
hyperboloid, 2622
Quadriplegia, pathology, 4370
Quadrupole
moment, 4370
potential, 4370
radiation, 4370
Quad unit, 4369
Quail, 4370–4371
breeding and processing of, 4286–4287
Qualitative analysis
chemical formulas, 1064–1065
chromatograph data reduction, 1098–1099
Quality control systems
chemical processes, 4371–4372
control charts, 1303–1304
operating characteristic, 3802
pharmaceuticals, 4048
statistical techniques, 4372–4376
talc processing, 5333
toluene processing, 5478
Quantic function, 4377
Quantile distribution, 4377
Quantitative analysis
chemical formulas, 1064–1065
chromatograph data reduction, 1098–1099
information theory, 2688–2689
Quantitative Precipitation Forecasts, 5826
Quantization
basic principles, 4377
of energy, superconductivity and, 5283
parallel analog-to-digital converter, 3934
pulse modulation, 4377
signals, 4377
Quantized Hall effect, 2375–2376
solid-state physics, 4880
Quantum, basic concept, 4377
Quantum chemistry, defined, 4377
Quantum-effect devices, compound semiconductors, 4716
Quantum efficiency, 4377
Quantum electrodynamics, 4377–4378
quarks, 4381–4382
Quantum field theory, subatomic particle physics, 3954–3955
Quantum liquids, defined, 3081
Quantum mechanics
atomic orbitals, 3820–3821
black holes, 710
Born approximation, 763
chemical elements, atomic structure, 1039–1042
degenerate state, 1450
electrical conductivity, 1712–1714
electron theory, 1780
exchange of particles, 1864
field theory, 1924–1925
Heisenberg representation, 2422
historical background, 4378–4380

Satellite Infrared Spectrometer (SIRS), Nimbus Satellite Program, 3647–3648
Satellites (communication and navigation)
components of, 4617–4621
geostationary earth orbit of, 2237, 4618–4624
global positioning systems in, 4625, 4628–4629
low-earth orbits for, 4618–4620, 4624–4625, 4627–4629
medium-earth orbits for, 4618–4620, 4624–4625
orbital characteristics of, 4618–4620, 4623
overview, 4617–4630
reconnaissance activities, 4630–4637
telephony
coaxial cable and, 5363
global telephone networks, 5371
wireless systems, 5358–5359
television technology and, 5390
Satellites (in space)
acquisition, 41
afterbody, 93
altimeters in, 161
Ariane space program, 2964–2976
BeppoSAX satellite, 605–606
biosatellite, 679
Chandra X-ray Observatory, 1020–1021
Clarke belt, 1125
Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) satellite, 1158–1161
Cloudsat system, 1172–1174
Compton Gamma-Ray Observatory (CGRO), 1260–1265
data collection, 3640–3651
Earth Observing System missions, 1649–1656
Terra satellite, 5401–5403
earth-orbiting satellites, data receiving and handling facilities, 1656–1663
earth's geoid and, 1638–1639
geodesy of earth and, 2216
Geostationary Operational Environmental Satellite (GOES) system, 2223–2237
geosynchronous orbit, 2238
global positioning systems (GPS), 2282–2292
Landsat Program, 1649, 2924
launch vehicles
air and ship-based systems, 2957–2963
Ariane program, 2964–2976
Russian programs, 2976–2982
U.S. expendable, 2983–2991
navigation satellites, 3592–3599, 4629–4630
Nimbus Satellite Program, 3638–3651
Orbiting Carbon Observatory (OCO) satellite, 3825–3826
Polar-Orbiting Environmental Satellite, 4187–4203
polar orbiting satellites, 4205
radar systems and, 4395–4396
rocketry and, 4556–4558
Rosat (Roentgen satellite), 4569–4570
search and rescue, 3640–3651
Seasat, 4669, 4696
Sputnik, 2284, 2978–2979, 5138–5143
Syncom Communication Satellites, 5317–5319
ultraviolet astronomy, 5575–5577
universe research by, 5010–5025
Satellites (planetary), 4617. *See also* Moon (Earth)
classification and characteristics, 4129–4131
of Jupiter, 406–415, 2164–2170, 2861–2865
of Mars, 3275, 4983
of Neptune, 3608–3611
of Saturn, 934, 4639, 4641, 4648–4654
Spitzer Space Telescope research, 5117
of Uranus, 5612–5615
Satellites (scientific and reconnaisance), 4630–4637
earth explorations by, 4986–4994
Seastar, 4696–4697
solar energy collection, 4875–4876
weather satellites, 5815–5824, 5827–5828, 5834–5835
Saturated fatty acids, 900, 1887
vegetable oils, 5653

Styrene-butadiene rubbers (SBR)
basic properties, 5233
compounding and pressing, 5233–5234
elastomeric properties, 1709
polymerization, 5233
raw materials, 5233
Styrene-maleic anhydride, 5234
Styryl dyes, 1611–1612
Subacute sclerosing panencephalitis, 5234
Subarachnoid hemorrhage, 1005
Subarachnoid space, structure and function, 990
Subarctic Pacific, 5234
Subatomic particles. *See also* Particle physics
amicron, 182
angular distribution, 241
annihilation, 246
antiparticles, 295
antiproton, 295
baryons, 565
beta decay, 611
beta particle, 612
betatron particle accelerator, 612–615
binding energy, 623–625
Bohr magneton, 740
bosons, 766
Bragg's rule, 781
bubble chamber, 821
classification, 3951–3955
cloud chamber, 1161
colliding-particle machines, 3959
Compton effect, 1260
cosmic rays, 1352
current research, 3955–3956
deuteron, 1482
double-beta decay, 4406
earth's magnetotail, 1637
exchange, 1864
families of, 3955–3956
fermions, 1897–1898
fusion power research, 2146–2149
hyperons, 2623
leptons, 3016
linear accelerators, 3957–3959
mesons, 3379–3380
muons, 3549
neutrino, 3623–3625
nucleons, 3718
pair production, 3904
particle accelerators, 3951, 3956–3957
positron, 4268
protons, 4340
psi particle, 4347
quarks, 4381–4382
sigma particle, 4770
soft X-ray laser system, 2946
spark chamber, 5088
stripped atoms, 471
structure and properties, 2372
superconducting super collider, 3960
synchrotron radiation, 3959–3960
tau particle, 5348
upsilon particle, 5601
xi particle, 5936
Sub-bituminous coal, basic properties, 1176
Subduction
ocean floor and crust, 3746
volcanoes and, 5748–5749
Subgraph, components and properties, 5234–5235
Subgrid-scale process, 5235
Subgroup analysis, statistical quality control, 4375
Subirrigation, 2826
Sublimation
applications, 5235–5236
crystallization, 1390–1391
freeze-drying, 2093–2094
heat of, 5236
nuclei, cloud formation and, 1162–1163
overview, 5235
percipitation and, 4300
Submarine cable systems, telephony and, 5364–5367
Submarine volcanoes, 5748
Submerged fermentation, bioprocess engineering, 656–657
Submersible vessels, ocean research, 3765–3769
Submillimeter Wave Astronomy Satillite (SWAS), infrared astronomy, 2703
Sub-multiplexing, analog switches, 217
Subpolar high, atmospheric pressure-gradient, 454
Subpolar low-pressure belt, atmospheric pressure-gradient, 453
Subroutines (computer system), 5236
Subsidence
defined, 5236
inversion, atmospheric, 452
Subsolar point, 5236
Substance testing, forensic chemistry, 2061–2062
Substandard propagation, radio energy, 4422
Substantia nigra, Parkinson's disease pathology and, 3944
Substitute natural gas (SNG), 3591
basic properties, 5236–5237
catalytic rich gas process, 5237–5239
hydrocracking-hydrogasification process, 5241–5242

methane-rich gas process, 5239–5241
methanol sources, 5242
noncatalytic partial-oxidation gasification, 5242
from solid waste, 5242
Substrates
enzymes, 1823
molecular and supermolecular electronics, 3484–3489
paints and coatings and preparation of, 3900
Subsurvace explorers, Mars missions, 3290
Subtilisins, serine proteases, 4330
Subtraction, defined, 5242
Subtractive color process
defined, 5242–5243
photographic emulsions, 4083
Subtropical countercurrent, 3762
Subunit vaccines, 5631–5632
Subwavelength illumination, light properties, 3026
Succession, plants, 5243
Successive-approximation converters, 219
analog-to-digital, 5243–5244
Succulents, classification, 5244
Suckers (fish), 5244
Sucralfate salts, ulcers and, 5568
Sucralose, 5244–5245
structure of, 5306
Sucrose
food applications of, 5248
structure and properties, 884–885
as sweetener, 5301
Sudden cardiac death, classification, 2405
Sudden infant death syndrome (SIDS)
epidemiology, 5245–5246
infant botulism, 2032–2039
Südliche Durchmusterung star catalogue, 5167
Sudsing modifiers, detergents, 1479–1480
Sufficient statistic, 5246
Sugar and sugar production
alcohols, 5250–5254, 5301–5302
bagasse byproduct, 540, 5250
bakery processes, 542
beet sugar, 596, 5248
cane sugar, 5246–5248
cell transport, 969
clarifying agents, 1124–1125
health and safety factors, 5248
industrial enzymes, bioprocess engineering, 665–667, 669
ion-exchange resins, 2797
maple syrup production, 3245–3254
molasses, 3480, 5250
price stabilization, 666–667
products and categories, 5249–5250
as sweetener, 5301
uses, 5248–5249
vinegar processing, 5688
Sugarcane plant, 5254–5255. *See also* Cane sugar
wax from, 5813–5814
Sulfapyridine, 4365
Sulfates
ammonium, 195–196
calcium, 850
cobalt, 1203–1204
copper, 1324
lead, 3002
magnesium, 3192–31932
oceanic deposits of, 5262–5263
organic compounds, 5268–5269
potassium, 4276
sodium, 4748
stannous sulfate, 5456–5457
stratospheric layer, 5221–5222
strontium, 5227
thorium, 5434
titanium dioxide process, 5471–5474
titanium refining, 5466–5467
vanadium, 5644
Sulfenamides, vulcanization accelerator, 4587
Sulfhydryl group, analytical chemistry, 224
Sulfides
ammonium, 194
antimony, 291

calcium, 850
cobalt, 1203
hydrogen sulfide, 2599
iron ores, 2806–2807
lead, 3002
magnesium, 3193
molybdenum, 3504
potassium, 4276
silicon, 4790
sodium, 4748
strontium, 5227
thorium, 5434
Sulfinpyrazone, gout, 2319
Sulfites
calcium, 850
food processing, 289–290
hyposulfurous acid/hyposulfites, 2629
magnesium, 3193
potassium, 4276
sodium, 4748
stannous sulfite, 5456
stratospheric ozone and, 5221
vanillin, 5646
Sulfonamides
competitive antagonism principle, 3993
diuretics, 1577–1578
drugs, 5255
historical background, 5255–5256
structure and properties, 183
Sulfonates, magnesium, 3193
Sulfonation, reaction mechanisms, 3841
Sulfone polymers, 5256
Sulfonic acid
basic properties, 5256–5257
insecticides, 2724
production, testing and application, 5257
toluenesulfonic acid, 5479
Sulfonylureas, herbicides, 2457
Sulfoxides, structure and properties, 5258
Sulfur
allotropic form of, 1038
applications, 5264–5265
in biological systems, 5267–5269
in coal, 1192–1195
dyes and dye intermediates, 1612
elemental sulfur, 5260
environmental issues, 5263–5264
extraction, 5261–5262
in fertilizers, 1908
fibers, 1918
history, 5258–5269
on Jupiter, 2860
mercury compounds, 3375
nomenclature and history, 1060
nonheterocyclic compounds, 3836
nutrients, 3445
ores, 5262
in petroleum, 4026
production, 5263
properties, 5259–5260
radioprotective agents, 4429–4432
rubber crosslinking, 4588
sources, 5260
steelmaking, 2821
substitute natural gas production and, 5240–5241
sulfates, 5262–5263
tarnish reactions from, 5343
terminology, 5263
thiols, 5428–5430
on Venus, 5669
Sulfur dioxide
clean coal conversion and emission of, 1189–1195
dechlorination, 1436
food processing, 289–290
Sulfur hexafluoride, global warming and, 2296–2297, 2354
Sulfuric acid
alkylation, 145–146
basic properties, 5266–5267
Sulfurous acid, 5269
Sulfur oxides, air pollution and, 4229
Sultriness, 5269
Sum, mathematical, 5269–5270
Sumac tree, 920–922
Summer lightning, 3037
Summer soil wetness, climatology and, 1143
Summer solstice, 5270
Sumner, James Batcheller, 5270
Sumner line, celestial navigation, 3593–3594, 5270
Sumptner principle, 5270
Sun
absolute magnitude of, 9
absorption spectrum, 13
apparent solar day, 305
bow shock of, 778–779
Campbell-Stokes recorder, 861
chromosphere, 1104, 5273–5274
corona, 1345, 5274, 5583–5584
basic principles of, 1336
discharge, 1336, 4606–4607
holes, 1336
mass ejections, 1336–1337
solar eclipse, 1691–1692
Ulysses Mission research on, 5583–5584
coronal holes, 1336
coronal mass ejections, 1336–1337
cosmic rays, 1351–1352
crepuscular rays, 1366
dimensions and physical data, 5272
earth's relationship to, 445
eclipses of, 1689–1693
Geostationary Operational Environmental Satellite (GOES) system exploration of, 2235–2237
green flash, 2353
heliopause, 2430
motion in space, 5277
omega sun mirage, 3792
Pers sunshine recorder, 4018
photosphere, 4092, 5272–5273
planetary motions around, 4131–4132
prominences, 4326, 5275–5276
skin cancer and, 4809
solar cycle, 4861
solar energetic particles, 4862
solar flares, 4876, 5276
interplanetary medium, 2764–2766
solar physics, 5279
solar seismology, 5277
solar time, 4877
space explorations of, 5003–5010
spectrum analysis, 5274–5275

Sun (*continued*)
spicules of, 5107
subsolar point, 5236
sunspots, 5275
synchronous orbits, 5272
zodiacal light, 5982–5983
Sun compass, 5270
Sun cross, 464
Sundial, 5271
apparent solar time, 5449–5450
Sundogs, 5271
Sun-earth sensors, spacecraft guidance, navigation and control, 4917
Sunfish, 5271
Sunflowers, botanical classification, 1255–1256
Sungrazer comets, 1244
Sunlight, defined, 5271
Sun pillar, 464, 5271–5772
Sunspots, 5275
weather technology and, 5835
Superabrasive wheels, properties, 7
Superacids, defined, 28–29
Supercharger, 5279–5280
Superconducting quantum interference device (SQUID), nuclear magnetic resonance/magnetic resonance imaging, 3690
Superconducting super collider (SSC), 3960
Superconductivity
applications, 5280
basic principles, 5280–5282
defined, 5280
electric motors, 3538–3541
energy quantization, 5283
Josephson junctions, 5282–5283
materials processing, 5283
rediscovery of, 5280
structural chemistry, 5283
theory, 5282
Superconductors
cryogenics, 1380
electric power production and distribution, 1733–1736, 1740–1741
Meissner effect, 3360
Supercooling
basic principles, 5284
percipitation and, 4300–4301
supersaturated vapor, 5287
Supercritical fluid extraction (SFE), trace and residue analysis, 5488–5489
Superelasticity, shape-memory alloys, 644–645, 4755–4756
Superelevation, basic principles, 5284
Superficial venous thrombosis, 1443–1444
Superfinishing, 5284
Superfluidity
basic properties, 5284–5285
cryogenics, 1380
Superheaters/reheaters, boiler system design, 746–747
Superheavy elements (SHEs)
classification and characteristics, 1036–1038
transactinides, 46
Superheterodyne principle, spectrum analysis, 5097
Superimposed river valley, 5285
Superior air, properties of, 105
Superior mirage, 5285
Superlattices
compound semiconductors, 4716
magnetic materials, 3198–3199
Supermolecular electronics
biological membranes, 3485
complex monolayer research, 3484–3485
enhanced device processing, 3486–3489
future research issues, 3489–3490
historical review, 3480–3481
Langmuir-Blodgett films, 3481–3484
metal-ion incorporation, 3485
nonlinear physics, 3486
solid-state physics, 4880
Supernovae
Chandra X-ray Observatory images, 1016–1020
classification, 3682–3684
Compton Gamma-Ray Observatory (CGRO), 1262–1265
death of stars and, 5599
Hubble Space Telescope images of, 2525, 2533
neutron stars, 3627–3628
Rosat (Roentgen satellite) exploration, 4570
star formation and evolution, 5153
supernovae 1987A and 1993J, 5285–5287
Superoxide dismutase, radioprotective agents, 4430
Superoxides
cesium, 1007
peroxides, 4011
Superparamagnetic contrast agents, magnetic resonance imaging, 3201
Superphosphates, in fertilizers, 1907–1908
Super-planets, Space Infrared Telescope Facility research on, 4944
Superplasticity, aluminum alloys, 171
Superposition
fluid dynamics, 2008
law of, 5287
Nernst principle of, 5287
Supersaturation
chemical, 5287
meteorological, 5287
percipitation and, 4300–4301
vapor, 5287
Supersonic aerodynamics, 88
airfoil characteristics, 5290
basic principles, 5287–5288
body characteristics, 5291
flow characteristics, 5288–5289
fluid dynamics, 2008
heating, 5292
noise, 5292
shock wave, 4766
stability and control, 5291–5292
wave categories, 5289–5290
wing-body combinations, 5291
wing span characteristics, 5290–5921
Superstring theory, subatomic particle physics, 3955
Supersymmetry, subatomic particle physics, 3954–3955
Supertwisted-nematic (STN) liquid crystal display (LCD), 3061–3062
Supervised learning, neural networks, 372–373
Supervisory control action, 1303
basic principles, 5292
Superwaves, atmospheric-ocean interface, 461
Supperation, pathology of, 5293
Supply current, 5292
Surface acoustic wave (SAW), molecular/supramolecular electronics, 3489
Surface Composition Mapping Radiometer, Nimbus Satellite Program, 3649
Surface currents (oceanic), 3762
Surface gravity wave, 5294–5296
Surface integral, 5652
Surface inversion, atmospheric, 452
Surface mining, coal, 1180–1181
Surface plasmon resonance (SPR), molecular/supramolecular electronics, 3488–3489
Surface properties and analysis
abrasion, 5
aerodynamics/aerostatics, 81
Gibbs division surface, 2266
integrals, 2737
liquid crystal display, 3075
Mars, Pathfinder Mission findings, 3977–3978
optical smoothness, 3818
parallel surfaces, 3935
patina, 3980
Petzval condition and surface, 4045
properties, 5293
quadric surface, 4369–4370
release agents and, 4491
Riemann surface, 4527
ruled surface, 4599
silicon, 4788
solid-state physics, 4880
specific surface, 5093
spherical surface, 5101
surface chemistry, 5293–5294
surface cleansing, detergents for, 1480–1481
surface conduction emitter, field emission displays, 1922
surface of constant phase, 5294
synclastic surface, 5317
tamm levels, 5337
thin film technologies, 5427
tribology, 5523–5525
Venus, 5665–5669
wave velocity surface, 5813
weather technology, 5827, 5833
Surface Science Package (SSP), Cassini-Huygens mission, 931
Surface tension
defined, 5295
Gibbs formula, 5295
surface chemistry, 5294
tensiometer, 5394–5395
Surface water
acid rain and, 25
inorganic contaminants, bioremediation, 678–679
nitrification and, 3657–3658
Surface Water Supply Index (SWSI), 1597
Surfactants
applications, 5296–5297
bakery processes, 542
basic properties, 5296
classification of, 5296
dentifrices, 1461
detergents, 1478–1479
food additives, 2028
soaps, 4837
sulfonic acids, 5257
Surge, electrical
defined, 5298
protection mechanisms, 1720
Surgeonfishes, 5298
Surge tank/vessel, 5298
Surgical procedures and techniques
arthroscopy, 343
automated lamellar keratoplasty, 484–485
blepharoplasty, 717–718
cancer treatment, 870
capsulotomy, 881
cardiovascular devices, 909
carpal tunnel syndrome therapy, 915
cataract extraction, 943, 5710
Cesarean section, 1007
circumcision, 1118
coronary artery disease, 1340
cryosurgery, 1380

curettage, 1394
debridement procedures, 1434
enucleation, 1821
extracapsular cataract extraction, 1869–1870
gallbladder and biliary tract diseases, 2171–2172
harelip correction, 2390
heart defects, 2406
hip replacement, 2475
intracapsular cataract extraction (ICCE), 2772
intraocular lens implants, 2777
intubation, 2779
laser eye surgery, 2952–2953
laser in-situ keratomileusis (LASIK), 2936
laser thermal keratoplasty (LTK), 2953
lobectomy, 3100
nephrolithiasis, 2888–2889
phacoemulsification, 943, 1869–1870, 3895
photorefractive keratectomy, 4091–4092
refractive eye surgery, 4475
scleral buckle, 4682–4683
shape-memory alloys for, 645
stereotactic surgery, Parkinson's disease, 3946
sutures, 5298
tracheostomy/tracheotomy, 5491
transplantation techniques
allografts, 1153–1157, 5511
artificial hearts, 2406–2407
autografts, 1153–1157, 5511
bone marrow transplantation, 758, 5512
corneal transplants, 5711
future research issues, 5515
graft survival, 5514–5515
heart, 2406–2407, 5513
history, 5511
immunogenetics and, 2662–2663
immunosuppression and, 5514
intestinal, 5513
kidney transplants, 2890, 5512–5513
liver, 3090–3091, 5513
lung, 5513
organ transplants, 5511–5514
pancreatic transplantation, 1489–1490, 3918, 5513
privileged sites, 5515
tissue engineering and, 5461–5462
xenografts, 5511
trephining, 5523
ultrasonic technology in, 5574
Surveillance systems, West Nile viruses, 5856
Surveying
azimuth, 509–510
benchmark, 599
differential leveling, 1519
global positioning system, 2291
level instrumentation, 3019
plane table, 4127
quadrant device in, 4369
transit surveying, 5499
traverse tables, 5516
triangulation, 5523–5524
Surveyor spacecraft
lunar exploration missions, 3127–3133
solar system research, 5001–5002
Survival analysis, mathematics, 3349–3350
Suspension bridge, structural characteristics, 800–802
Suspensions
polymerization, 4246
sedimentation and, 4702–4704
water pollution and, 5798
Suspension systems, colloids, 5298
Sutherland's formula, viscosity properties, 5705
Sutures, 5298
Suzaku mission, universe research by, 5014–5015
Svedberg, Theodore, 5298
Svobodnyy Spaceport, 4951
Swallow (bird), 5298
Swallow float, 5298
Swallowtail butterfly, 5298
Swamp cypresses, 1414–1415
Swamps, 5298–5299
forests and, 2064
muskeg, 3555
Swans, classification, 5792
Swarts reaction, 5299
Sweden, X2000 high-speed train, 4436–4437
Swedish Lamella thickener, 5422
Sweepback (aircraft wing), 5299
Sweep circuit, 5299–5300
Sweeteners
enhancers, inducers, and inhibitors, 5310
food additives, 2029
formulating and processing applications, 5310–5311
fructose, 884, 2119–2120
honey, 2494–2495
ion-exchange resins, 2797–2798
maple syrup, 3241–3254
molasses, 3480
nonnutritive sweeteners, 5302–5310
nutritive sweeteners, 5300–5302
overview, 5300
saccharimeter, 4605
starch conversion into, 5171–5172
sucralose, 5244–5245
sugar, 5246–5250
sugar alcohols, 5250–5254
taste transduction mechanisms, 5311–5312
vanillin, 5646–5647
Sweetgum tree, 5312
Sweetness potency, defined, 5300
Sweet potato, 5312–5313
Sweetsop/sugar apple, botanical classification and characteristics, 246
Swelling, ion-exchange resins, 2793
Swells, atmospheric-ocean interface, 460–461
Swept-tuned spectrum analyzer, 5097–5098
Swift Gamma Ray Burst Explorer, 5015
Swift (lizard), 5313
Swifts (birds), 5313
Swine, characteristics and classification, 5313–5315
Switchhook, telephony, 5359–5360
Switching systems
electric power production and distribution and, 1735–1740
ferreed switching device, 1901
field-effect transistors (FETs), 1920
gate-turnoff switch, 2194
light-coupled switch, 3027
limit switch, 3047–3048
magnetostrictive limit switch, 4346
organic semiconductors, 4723
proximity and object detection, 4345–4346
rectifiers, 4466
servo systems, 4739–4742
silicon controlled switch, 4794
tactile feedback, 5332
telephony
current technologies, 5357
customer premises equipment, 5360
equipment components, 5368–5370
ultrasonic switches, 4346
Wiegand-effect switches, 4346

Testosterone
  classification, 2503–2507
  structure and properties, 228–229
Testudinata (turtles), 5404
Tetanus, epidemiology and pathology, 5404–5405
Tethered Satellite System (TSS), solar explorations, 5009
Tethys (Saturn's satellite), 4652
Tetraacetate, lead, 2999
Tetrachloride-reduction process, titanium refining, 5467
Tetrachoric correlation, 5405
Tetracyanoquinodimethane (TCNQ), molecular/supramolecular electronics, 3487–3488
Tetracyclines, 265
  antimalarial drugs, 3217–3218
Tetradic structure, 5405
Tetradymite, 5405
Tetrafluorides
  chromium, 1103–1104
  lead, 3000
Tetraglycidylmethylenedianiline-derived resins, 1835
Tetrahedrite, 5405
Tetrahydrofuran (THF), manufacturing of, 1849
Tetralogy of Fallot, 2406
Tetraodon poisoning, 2038
Tetraorganotin compounds, 5457
Tetrodes, electron tube device, 1780
Texaco coal gasification process, clean coal conversion and, 1193
Texas leaf-cutting ant, 292
Text files, properties of, 1927–1928
Textiles
  bleaching agents, 713–716
  cotton, 1358
  detergents for, 1479–1480
  dyes and dye intermediates, 1620–1623
  fiber properties and classification, 1914–1918
  filaments, 1925
  filler, 1930
  flame retardants, 1963–1965
  hexitols, 5254
  laser applications in, 2951

polyesters, 4239–4241
pyridines, 4365
release agents, 4492
silk, 4796–4798
tissue engineering and technology from, 5463
viscose process, 5704–5705
Textual clocks, 1151
Thalamus, structure and function, 982
Thalassemias, iron metabolism, 2812
Thallium
nomenclature and history, 1061
structure and properties, 5405–5406
Thames Barrier, 1993
Thaumatin, structure of, 5308–5309
Theiler, Max, 5407–5408
Theileriasis, pathology, 5406–5407
Theodolite, 5408
Theorem, 5408
Theoretical astrophysics, 442
Theoretical plate, 5408
Therapeutic immunization, 5656
Thermal, definitions, 5409
Thermal and evolved gas analyzer, Phoenix Mission to Mars, 4062
Thermal conductivity
ablative materials, 3–4
copper, 1322–1324
definitions, 5409
diamond, 1493–1495
diathermal wall, 1499
foamed plastics, 2021–2022
gas analyzers, 2186–2187
heat transfer, 2416–2417
Thermal cracking, hydrocarbons, 1363–1364
Thermal degree, 1451
Thermal diffusion/diffusivity, 1522–1523
defined, 5409
heat transfer, 2417
uranium-235 enrichment, 5607–5608
Thermal drying, biosolids treatment, 681–682
Thermal effects, roofing materials, 4564–4565
Thermal efficiency, 5409–5410
Thermal emissions, radio astronomy, 4418
Thermal Emission Spectrometer (TES), Mars Global Surveyor (MGS) Mission, 3328
Thermal energy
cogeneration, 1216
Compton rule, 1265
ocean thermal energy conversion, 3769–3775
solar energy and, 4870–4875
storage systems, 4872
Thermal evaporation, metallic coatings, 3383
Thermal expansion coefficient, 5410
Thermal gradient, 5410
Thermal insulation, 2730–2735
materials and properties table, 2734–2735
systems and materials, 2731–2735
Thermal loop systems, Space Technology 8 mission research, 5085–5086
Thermally enhanced oil recovery (EOR), petroleum production, 4036–4037
Thermal mass flowmeter, 2004
Thermal noise, 3669
Thermal plasmas, 4160
Thermal preservation technology, food preservation, 2051–2052
Thermal Protection System Advanced Development Project, Constellation Program (NASA), 1294
Thermal protection systems
ablative materials, 4
spacecraft design and, 4906
Stardust Mission, 5183
Thermal resistance, thermal insulation, 2733
Thermal spray, metallic coatings, 3382
Thermal stabilization/stability, 5410
atmospheric-ocean interface, 460
ion-exchange resins, 2794–2795
liquid-solid extraction, 1874–1875
sulfoxides, 5258
Thermal theory, flame resistance, 1964
Thermal tide, atmospheric, 459
Thermal tubular reactors, industrial applications, 4462–4463
Thermal variables, 5648
Thermal watt converter, electric power measurement, 1726–1727
Thermionic conversion, 5410
Thermionic regulation and switching devices
power supply, 4294–4295
space charge, 4901–4902
Thermistor, properties and components, 5410–5411
Thermite, 5411
Thermochemistry
chemical reaction rate, 1065–1068
defined, 5411
hydrogen production, 2597
ozone, 3878
Thermocline, 5411
Thermocouple
basic principles, 5411–5412
thermoelectric energy conversion, 5417–5418
thermopile, 5420
vacuum systems, 5636–5637
Thermodynamics
absolute zero and, 10–11
adiabatic process, 58–59
of atmosphere, 448–449
basic principles, 5413
Carnot cycle, 913
chemical equilibrium, 1063–1064
Clapeyron-Clausius equation, 1122
Clausius equation, 1127
Clausius law, 1127
closed system, 1158
conservation of energy, 1292
diagram, 5412–5413
dielectric heating, 1502
Dulong/Petit law of specific heats, 1608
enthalpy, 1817–1819
equations of state, 1836–1837
equilibrium, 1838–1839
first law of, 5414
fluctuation, 2007
heat sink, 2415
ideal system, 2639
Kelvin unit, 2871
mixing line analysis, 3462
moist static energy, 3479
nucleation, 3716
order-disorder theory, 3827–3828
polytropic processes, 4257–4258
rocket propulsion theory, 4552–4554
saturation mixing ratio, 4638
second law of, 5414
stationary state, 5186
statistical, 5415–5416
of steam, 5187
temperature scales and standards, 4448, 5393–5394–5394
third law of, 5414–5415
Thomson principle, 5433
zeroth law, 5413–5414
Thermoelectricity
cells, 4292
cooling systems, 5416–5417
defined, 5418
energy conversion, 5417–5418
Thermoforming, food packaging containers, 2047–2048
Thermofor process, 5418
Thermograph/thermography, principles and applications, 5418–5419
Thermogravimetric analysis (TGA), 5419
Thermogravitational column, diffusion, 1522–1523
Thermohaline circulation, 5419–5420
Thermoluminescence, radioactive dating and, 4416
Thermomechanical properties, shape-memory polymers, 4757–4759
Thermometers
acoustic, 39
bimetal thermometer, 622
definitions, 5420
filled-systems, 5420
katathermometer, 2870
liquid-in-glass thermometer, 3079
maximum thermometer, 3352
minimum thermometer, 3457
radiant energy, 4398
radiation thermometry, 4401–4403
rare gases in, 4456
resistance thermometer, 4501–4502
temperature scales and standards, 5393–5394
Townsend support, 5485
ultrasonic, 5572
Thermometric titration, 5475
Thermonuclear reactions, proton-proton reacation, 4340
Thermophilic anaerobic digestion, biosolids treatment, 680–682
Thermophone, 5420
Thermopile, 5420
Thermoplastics
definition, 5420
extrusion, 1878
lactic acid, 2911
natural rubber, 4593–4594
organic polymers, 4253
polyamide-imide resins, 4235
polyarylates, 4235
polybutylene resins, 4236
polybutylene terephthalate polyesters, 4236
polycarbonates, 4236–4238
polyether-etherketone, 4241–4242
polyetherimide, 4242
polyethylene, 4242–4243
polyvinylidene chloride, 4260
resins, 4498
shape-memory polymers, 4757–4759
styrene-maleic anhydride, 5234
talc additives, 5333
urethanes, 5619–5620
vinyl ester resins, 5691–5693
wood-thermoplastic composites, 5921–5922
Thermosets
adhesives, 58
definition, 5420
permanent-press resins, 4006
vinyl ester resins, 5691–5693
wood composites, 5917–5921
Thermosphere, 5420
Thermosphere, Ionosphere, Mesosphere Energetics and Dynamics (TIMED), solar explorations, 5006
Thermotropic atmosphere, 449
Thermotropic liquid crystals, 3077–3078
Theropods, bipedalism in, 688–690

Theta function, 5421
Theta pinch experiment, fusion power research, 2147–2149
Thevenin theorem, 5421
Thiamides, structure and properties, 183
Thiamine (vitamin B_1), structure and properties, 5729–5730
Thiazides, diuretics, 1575
Thickeners
  basic properties and classification, 5421–5422
  dentifrices, 1461
  mixing processes, 1126
Thickness measurement and gaging systems, 5422–5424
  ultrasonics, 5572
Thief ant, 293
Thin, definitions of, 5424
Thin-film electroluminescent (TFEL) displays, 1750–1752, 3421
Thin-film technologies
  adhesion, 5427
  electrical properties, 5427
  electronics, 5425–5426
  ferroelectric materials, 1903–1904
  fuel cells, 2130–2131
  magnetic materials, 3198, 5426
  medical applications, 5427
  morphology and density, 5427
  nitrides, 3655
  nucleation, growth, and mechanical properties, 5425
  optics, 5425, 5427
  organic semiconductors, 4721–4722
  overview, 5424
  photovoltaic cells, 4095–4096
    solar energy, 4875
  residual stress, 5427
  surface coverage, 5427
  ultraviolet stabilizers, 5582
  vacuum deposition, 5638
  vitreous silicas, 4785
Thin-film transistors (TFTs)
  cadmium selenide, 3071
  liquid crystal display, 3064–3067
    amorphous silicon, 3068–3071
Thin-layer chromatography (TLC)
  basic principles, 1096–1097, 5427–5428
  trace and residue analysis, 5489
Thin-lens relationships, 5428
Thinners
  paints and coatings, 3898
  properties of, 5428
Thiocarbamate herbicides, 2457
Thiocarbonate, potassium, 4276
Thiocyanates
  ammonium compound, 194
  potassium, 4276
Thiocyanic acid, 5428
Thioethers, 5428
Thiokol® rubber, 1710
Thiols
  chemistry and nomenclature, 5428–5429
  physical properties, 5429
  preparation, 5429
  as radioprotective agents, 4428–4432
  reactions, 5429–5430
    toxicology and handling, 5430
Thiophene/thiophene derivatives
  pharmaceutical applications, 5431–5432
  properties and nomenclature, 5430–5431
  reactions, 5430–5431
  toxicity, 5431
Thiosalicylic acid, 4607
Thiosulfates, sodium, 4748, 4951
Thioureas
  structure and properties, 5432
  vulcanization accelerator, 4588
Third generation technology, wireless communications applications, 5907, 5910–5911
Thistle butterfly, 8398
Thiuram sulfides, vulcanization accelerator, 4588
Thixotropic colloids, 1224
  rheology, 4516
Thixotropic fluids, defined, 2007–2008
Thixotropy, properties of, 5432
Thomas-Fermi differential equation, 5432
Thomson, J. J., 5432
Thomson determination, electron theory, 1779
Thomson parabola method, 5432–5433
Thomson principle, 5433
Thomson's law, 5432
Thorax, anatomy, 5433
Thorianite, 5433
Thorite, 5433
Thorium
  actinides, 45–46
  applications of, 4408–4409
  nomenclature and history, 1061
  radioactive dating using, 4414–4416
  refractory materials, 4478
  series of elements, 1036
  structure and properties, 5433–5434
Thor Missile program, 2985
Thorns (of plants), 5194
Thorny-headed worms, classification, 14
Thrasher bird, 5435
Three-body problem, 5435
Three-dimensional computer animation and graphics, 1270–1273, 1276–1277
Three-phase equilibrium, 5435
  triple point, 5533
Three-plus-one address, computer systems, 56
Three-position controller, 1305
Threonine proteases, 4330–4331
Threshold decoding, information theory, 2694
Threshold detector
  basic components, 5435
  comparator amplifier, 1252
Threshold illuminance, 5435
Threshold values, thiols, 5430
Thrips, zoological classification, 5435–5436
Throat, anatomy, 5436
Thrombin
  basic properties, 5436
  blood coagulation mechanisms, 732–735
  central nervous system protection and, 990
Thromboembolism, anticoagulant therapy, 276
Thrombolytic agents
  coronary artery disease, 1340
  coronary thrombosis, 1342–1343
Thrombomodulin, thrombosis and, 728–729
Thromboplastin, blood coagulation mechanisms, 731–735
Thrombosis, 331
  cerebral, 1004
  clotting mechanisms and, 728–729
  coronary, 1341–1345, 5437
  deep vein, 276, 1443–1444, 5436
  epidemiology and pathology, 5436–5437
  peripheral, 5437
  pulmonary, 5437
  recurrent miscarriage syndrome, 5437
  renal vein, 2888
  retinal vascular, 5437
  stroke and, 5437
Thrombus, defined, 327
Throttle, 5438
Throughfall, forests, hydrologic cycle and, 2063
Throughput, 5438
Through-type truss bridge, structural characteristics, 800
Throwing power, 5438
Thrush (bird), 5438
Thrust, 5438
  helicopter aerodynamics, 2425
Thulium
  nomenclature and history, 1061
  as rare earth element, 4450–4455
  structure and properties, 5438–5439
Thunderstorms
  blue jets, 736
  breaking-drop theory of charge separation, 787
  Chubasco, 1109
  cumulonimbus clouds, 1166–1167
  electrical breakdown, 1711
  electricity during, 1721
  flooding and, 1992–1993
  green thunderstorm, 2355
  gust front, 2365–2366
  initiation mechanism, 2115
  ion-capture theory, 2788
  lightning, 2115–2116, 3041
Thyme, 5107
Thymoma, 5440
Thymopoietin, 5439
Thymosin, 5439
Thymus gland
  anatomy and function, 5439
  disorders of, 5440
  endocrine system and endocrinology, 1809–1810
  physiology of, 5439–5440
Thyratron rectifier, 4466
Thyristor devices
  basic properties, 5441
  electric power production and distribution, 1738–1740
  servo drives, 4739–4741
  solid-state variable-speed drives, 4739–4740
Thyroid gland
  disorders, 5441–5443
  iodine biochemistry, 2787–2788
  radionuclide scanning, 4412
  structure and function, 5441
Thyroid hormones (TH), structure and classification, 2502–2507
Thyroiditis, pathology of, 5443
Thyroid stimulating hormone (TSH)
  chronic fatigue syndrome diagnosis, 1106–1107
  classification, 2503–2507
  thyroid disorders and, 5442–5443
Thyrotropic hormone, 4123
Thyroxine
  classification, 2503–2507
  structure and function, 5441–5443
Tick-borne encephalitis viruses
  epidemiology and pathology, 341–343, 2442
  as flavivirus, 1973
  Lyme disease, 3157–3158
Ticks
  bites from, 1468
  classification of, 5443–5444
  repellents against, 4495
  sheep tick, 4764
Tidal waves, history of major, 1644

Tides
bore, 763
clock, 1150
coastal waters, 1197–1198
direct tide, 1555
earth tide, 1681
energy sources from, 3769
estuaries and, 1845–1847
gages, 5448–5449
mechanics of, 5449
ranges of, 1642
red tides, 4468
storm surge, 5218
tidal energy, 5444–5448
Tiger, zoological classification and characteristics, 952
Tiger beetle, 5449
Tiger's eye, 951
Tillage operations, grasshopper control, 2339–2340
Till sediments, 5449
Tiltmeter, 5449
Tilt table, 5449
Timation system, global positioning system and, 2285
Timber
dams, 1422
redwoods, 4470
wood composition and classification, 5922–5924
Time. *See also* Geologic Time Scale
basic principles of, 5449–5450
categories of, 5449–5450
chronograph and, 1108
chronometer, 1108
circadian clock, 1113–1114
clocks, 1147–1151
combustion principles and, 1237–1243
constant, 5451
transfer function, 5494
day definitions, 1430–1431
delay, 1453
discriminator, 5451
display methods, 1151

Triethylene glycol, 1852
Triggered lightning, 3037
Triglycerides, drying oils as, 1603–1604
Triglycidyl p-aminophenol-derived resins, 1835
Trigonometry
  basic principles, 5530–5531
  hyperbolic function, 2621–2622
  inverse function, 2779–2780
  Laplace transform, 2930
  method of components, 3407
  spherical, 5101–5102
  trigonometric curve, 5529
  trigonometric function, 5529–5530
Trihalides
  gallium, 2173
  structure and properties, 291, 326
Trihydrate, lead, 2999
Trihydric alcohols, 128
Triiodothyronine, structure and function, 5441–5443
Trilobata (trilobites)
  habitat and diversity, 5532
  paleontology, 2782–2783
  phylogeny and geological history, 5532–5533
  structure and classification, 5531–5532
Trim, airplane, 5533
Trimethylsulfoxonium salts, 5258
Trimmer capacitor, 5533
Trinitrotoluene (TNT)
  explosives, 1867–1868
  structure and properties, 5476–5477
Triodes, electron tube device, 1780
Trioganotin compounds, 5457–5458
1,2,4-Trioxacycloalkanes, 4013
Triphylite, 5533
Triple bonds
  basic properties, 5533
  chemical elements, 1050–1051
Triple-effect steepwater evaporator, starch conversion, 5171–5172
Triple point, three-phase equilibrium, 5533
Triple X syndrome, X-chromosome and, 5934
Tripolite, 5533
Trisectrix of Maclaurin, 5533
Trisomy 21, 1587–1588
Tristimulus values, 5533
Tritium
  isotopic structure, 5533
  nuclear fusion, 3687
Triton-based decay modes, 4407
Triton (Neptune's satellites), 3608–3611
Trivalent chromium, compounds from, 1103
Trochoid path, 5533
Trogon bird, 5533
Trogoniformes, 5533–5534
Trojan asteroids, 389–390
Trophallaxis (insect feeding), 5534
Trophic state
  lakes, 2914
  properties, 990
Trophosome family, 5534
Tropical air
  fronts and storms, 2111–2112
  properties of, 104
  weather technology and, 5828–5829
Tropical diseases
  definitions and classification, 5534–5535
  ulcers, 5568
Tropical fish, 5535
Tropical forest, biomes, 647–648
Tropical Prediction Center, 5828
Tropical Rainfall Measuring Mission (TRMM), 1649
  earth exploration and, 4990
  instrumentation, 5536–5537
  Microwave Imager, 1655
  overview, 5535–5536
  research accomplishments, 5537–5538
Tropical storms
  cyclones, 2117
  mapping of, 2114
Tropical Wind Energy Conversion and Reference Level (TWERLE), Nimbus Satellite Program, 3649–3650
Tropical year, 5538
Tropism, zoological classification and, 5538
Tropopause
  atmospheric shell, 470
  basic properties, 5538
  defined, 447
Troposphere
  air pollution modeling and, 4220–4224
  atmospheric shell, 470
  defined, 446–447, 5338
  ozone in, 3879, 5338–5339
Tropospheric Emission Spectrometer (TES), Aura Mission, 479
Trough, meteorological, 5539
Trough/line-focusing concentrators, solar energy systems, 4867–4869
Trout, 5539
Truck haulback surface mining, coal, 1180–1181
Trucking transport, coal, 1184
True-airspeed indicator, components and application, 122–123
True north, 5539
Truncation, mathematical, 5539
Truncus arteriousus, 5539
Trunk, definitions of, 5540
Trunk lines
  crude oil pipelines, 4043–4044
  telephony systems, 5366
Trusses
  framed bridges, 800
  statics of, 5185–5186
  structural properties, 5540
Trusted gateways, firewalls, 1940
Trypanosoma cruzi, 1008–1010
Trypanosomiasis
  Chagas disease, 1008–1010
  epidemiology and pathology, 92–93, 5540–5541
Trypsins, serine proteases, 4330
Tryptamines, hallucinogenic drugs, 2380–2381
T section, 5541
T-section filter, 1932–1933
Tsetse fly
  classification, 5541
  trypanosomiasis, 92–93
Tsiklon space launch system, 2977–2982
Tsiolkovsky, Konstantin E., 5541–5542
T stars, properties of, 5162
Tsunami, 5542–5543
  volcanic eruptions and, 5752
Tsushima current, 3762
Tuatara, 5543
Tubal pregnancy, 2314
Tuberculosis
  arthritis, 333
  epidemiology and pathology, 5543–5544
  historical background, 5544
  modern reemergence of, 5544–5545
  skin, 1467
Tubular reactors
  design and components, 4460
  fixed-bed reactors, 4463
Tubuliform glands, 5545
Tubulin active drugs, chemotherapeutics, 1071
Tucotuco, 4560–4561
Tuff, volcanic, 5545
Tukon hardness test, 2390
Tularemia, 5545
Tumble-bug, 5545
Tumorigenicity assays, 5545–5546
Tumor necrosis factor (TNF)
  family, 1418
  receptor signaling pathways, 1418
Tumors
  adenocarcinoma, 56
  adenoma, 56, 62
  adrenal carcinoma, 62
  angioma, 239
  basal cell carcinomas, 866
  bronchiolar/alveolar carcinoma, 865–866
  choroidal melanoma, 1095
  Conn adenoma, 63
  of eye, 5711–5712
  fibroma, 1919
  fibroneurosarcoma/fibrosarcoma, 866
  Kaposi's sarcoma, 99, 2465
  lymphoma/lymphosarcoma, 3169–3170
  melanoma
    choroidal melanoma, 1095
    epidemiology and pathology, 3361–3364
    of eye, 5711–5712
    skin cancer, 4809
  mesothelioma, 865–866
  myeloma, 758, 3467
  papillomaviruses, 3929–3930
  pheochromocytoma, 64
  polyps, 4255
  retinoblastoma, 4506–4507
  sarcoma, 4617

Tumors (*continued*)
squamous cell carcinoma, 866
thymoma, 5440
thyroid gland, 5443
tumorigenicity assays, 5545–5546
viral-induced, 3792–3794
Tuna, 5547–5548
Tunder, mechanisms, 2116
Tundra
biomes, 647
characteristics of, 5548
Tuned amplifiers, 210
Tungstate
magnesium, 3193
sodium, 4748
Tungsten
nomenclature and history, 1061
powder metallurgy, 4289
steelmaking, 2821
structure and properties, 5548–5551
tantalum alloys, 5340
Tung tree, 5548
Tunguska meteor site, 398
Tuning fork, characteristics, 5551
Tuning fork gyroscope, spacecraft guidance, navigation and control, 4914
Tunnel engineering
Eurotunnel, 5552–5555
global positioning systems, 4630
overview, 5551–5552
Tunnel vision, mechanics of, 4004
Tupelo trees, 5555
Turacos (birds), 1392, 5557
Turbellaria (worms), 5557
Turbidimetry, basic principles, 5557
Turbidity, defined, 5557
Turbinado sugar, 5249–5250, 5301
Turbine flowmeters, 2002
Turbines and turbine engines
expansion turbines, 2190–2191
gas turbines, 2187–2190
configuration and properties, 2187–2190
high-temperature gas-cooled nuclear reactor, 3703–3704
management and maintenance, 2190
hydraulic turbines, 2586–2587
hydroelectric power, 2586–2587
stages of, 5146
steam turbines, 5557–5559
wind power, 5885–5886
Turbocharging, diesel engines, 1504–1507
Turbo code, spacecraft telecommunications and, 4909
Turboexpanders, configuration and properties, 2190–2191
Turbofan engines
basic principles, 113–115
defined, 5559
Turbojet engines, design fundamentals, 112
Turbopause, 5559
Turboprop engines, basic principles, 113
Turbot (fish), 1967–1968
Turbulence and turbulent flow
aerodynamics/aerostatics, 91
aircraft, 103
atmospheric, 470–471
basic principles, 5559
bivane measurements, 708
blending height, 716

Zeeman, Erik Christopher, 5969
Zeeman effect, 5969
chemical elements atomic structure, 1040–1042
electron theory, 1779
Zein, 5959
Zeisberg concentrator, 5959
Zeisel determination, 5959
Zeisel reaction, 5969
Zeitgeber, 5970
Zelkova tree, 2371
Zellweger's syndrome, 5970
Zener current, 5970
Zener diode, 5970
Zener voltage, 5970
Zenit-2 launch vehicle, 2979–2982
Zenith, 5970
Zenith telescope, 5970–5971
Zeolites
adsorption and liquid separation, 74–75
classification, 5971
feedwater softening process, 1893–1894
molecular sieves, 3492–3494
water softening, 5787
Zerewitinoff determination, 5971
Zero, absolute, 10–11
Zero, value of, 5971
Zero error, 5971
Zero gravity, 5971
Zero-level address, computer systems, 56
Zero-order reaction, 5971
Zero point energy, 5971
Zero point entropy, 5971
Zeroth law, thermodynamics, 5413–5414
Zero tolerance, 5971
Zeta potential, 5971–5972
Ziegler, Karl Waldemar, 5972
Ziegler method, 5972
Ziegler-Natta catalysts
basic properties, 5972
polymerization, 940–941
stereoregular polymers, 5205–5206
Zigzag ridge, 5972
Zimmerman reaction, 5972–5973
Zinc
applications, 5974–5975
in biological systems, 5977–5978
compounds, 5975–5976
dezincification, 1484
extractive metallurgy, 5973–5974
galvanizing process, 2175–2176
health and safety, 5976
insecticides, 2723
magnesium alloys, 3189
molybdates, 3504
nomenclature and history, 1062
nutrients, 3446
peroxide, 4008
phosphate coatings, 1317–1318
pigments, 4110–4111
sherardizing, 4764
structure and properties, 5973
transporters, 5978–5979
Zinc borate, flame retardants, 1961
Zinc bromide, structure and properties, 810
Zinc finger proteins, 5976–5977
Zincite, 5978
Zingg pebble classification, 5979
Zipf's law, 5979
Zircon, structure and properties, 5979
Zirconates, lead, 3002
Zirconia, refractory materials, 4478
Zirconium
applications, 5981–5982
compounds, 5980–5981
health and safety, 5981
hydride, 2583
magnesium zirconium silicate, 3193
nomenclature and history, 1062
porcelain, 4264
specifications and standards, 5981
steelmaking, 2821
structure and properties, 5979–5980
tantalum alloys, 5340
Zodiacal light, 5982–5983
Zodiac belt, 5982
Zoisite, 5983
Zollinger-Ellison syndrome, 5983
Zonal aberration, 5983
Zonal flow, atmospheric circulation, 452
Zond Missions
lunar exploration, 3126, 3133–3137
Mars exploration, 3263
to Venus, 5670
Zone bit, 707
Zone electrophoresis, 1781–1783
Zone plate, 5983
Zone refining, 5983–5984
Zones, definitions, 5983
Zone time, 5984–5985
Zoochlorella, 5985
Zoogeography
biomes, 646–648
defined, 5985
Zoological sciences
Acoelomata order, 30
alternating generations, 160–161

Zoological sciences (*continued*)
antenna systems, 257
appendages, 306
biochemistry, 629–630
biogeography, 637–640
biological level classifications, 640
bipedalism, 686–690
burrowing habits research, 836–837
ecological association, 386
helminthology, 2433
hemichordata, 2435
heredity, 2458–2460k
homoiothermy, 2494
regeneration, 4483–4485
Zoonotic viruses
filoviruses, 1931
hemorrhagic fever viruses, 5693–5694
rabies, 4390–4391
Zooplankton, classification of, 4132–4133
Zoospore, 5985
Zoraptera, 5985
Zsigmondy, Richard, 5985
Zsigmondy reagent, 5985
Zwitterion ions
basic properties, 5985
detergent surfactants, 1478–1479
isoelectric focusing, 1782
Zworykin, Vladimir Kosma, 5985
Zygomatic arch, 5985
Zygomycosis, opportunistic infections, 3560
Zygospore, 5985
Zygotes, 5985–5986
cloning and, 1152
Zylon, on Mars Exploration Rovers (Spirit and Opportunity) mission, 3308
Zymogens, blood coagulation and, 731–732
Zymosterol, 5209
